The periodicity of Raynaud's disease is one of its most remarkable and characteristic features. The attacks, which are then necessarily of short duration, sometimes come on every day, or even several times a day; often they occur at longer and irregular intervals, say, of a week or two; sometimes they are separated from one another by prolonged periods of freedom. Patients suffer chiefly in cold weather and during the winter months; and attacks are often induced by some definite exposure to cold. They may begin at any time in the four-and-twenty hours, but rarely when the patient is warm in bed. And they tend, especially if no precautionary measures be adopted, to increase in frequency and severity. Females seem to suffer more than males; and children perhaps more than adults. But the disease may show itself at any age. Those who are, or become, liable to the disease often suffer from languid circulation; and in a few instances diabetes has co-existed with it.

*Treatment.*—It is obvious that patients suffering from Raynaud's disease should, in cold weather especially, be very warmly clad, should wear flannel underclothing, and protect their hands and feet with thick woollen gloves and socks, and should be careful not to expose themselves to cold winds or cold draughts. Regular exercise is desirable; but it must be borne in mind that exercise alone does not in many cases prevent the occurrence of the local anæmia. Habitual warm baths, with friction and shampooing, are certainly beneficial. In severe cases removal, for

the winter months, to some warm climate, or even permanent residence abroad, may be needed. Tonics and good diet are clearly indicated. Drugs which cause dilatation of arteries, such as belladonna, nitrate of amyl, and nitro-glycerine may possibly be of service. The continuous galvanic current, either passed through the spine to the affected region, as Raynaud advises, or applied locally, as others recommend, seems to have marked beneficial effect when employed during the presence of an attack; and its persistent use is to be recommended in the treatment of persons liable to frequent recurrences.

---

## XII. SCURVY. (*Scorbutus*)

*Definition.*—Scurvy may be regarded as a peculiar form of anæmia arising from deficiency of vegetable diet, and attended with a tendency to the occurrence of hemorrhages, profound impairment of nutrition, and great mental and bodily prostration.

*Causation.*—Scurvy formerly occurred largely among sailors during long voyages. It has often broken out in armies on active service and among populations suffering from famine. It still occurs from time to time under these various conditions; and is occasionally met with as a sporadic affection among persons who are ill-fed, or whose diet has been, from some cause or other, too exclusively animal. It is needless to go into a history of scurvy, or to discuss the various hypotheses which have been propounded in reference to its causation. It will be sufficient to state that its origin has been clearly traced to insufficiency or total want of fresh vegetables; but among these must not be included corn or other graminaceæ, or peas. It is still uncertain to what constituent or constituents, common to vegetables, their virtue is due. Dr. Garrod believes it to reside in the salts of potash; others maintain that it dwells in the citric and other vegetable acids which they so often contain. There are objections, however, to both of these views; for the antiscorbutic powers of vegetables do not appear to be proportionate to the potash salts they contain, and potash salts alone are probably inefficacious; and potatoes, which are powerfully antiscorbutic, are devoid, or nearly so, of vegetable acids. The constant use of salt meat, and long-continued exposure to privation and other such causes of ill-health, can only be regarded as indirectly favouring the production of scurvy.

*Symptoms and progress.*—The early symptoms of scurvy may be easily misunderstood when presented by sporadic cases; but they cannot fail to attract attention when they arise simultaneously or in rapid succession among a number of persons equally exposed to the conditions which are liable to give origin to the disease. They are: rapidly progressive anæmia, indicated by a dirty-looking, pallid, sallow, or earthy aspect; growing indisposition for bodily exertion; pains of a rheumatic character in the back and limbs; and mental apathy or depression; while probably the

tongue continues clean, though becoming large, flabby, and indented by the teeth, the appetite remains good, and the bowels are constipated. But soon other phenomena arise: petechial spots appear, first on the lower extremities, and then on other parts of the surface; and to these presently succeed large subcutaneous extravasations, and sooner or later colourless puffy swellings, which seem to be due to deeper-seated and more copious hemorrhages, and the nature of which gets revealed ere long by the occurrence of bruise-like staining of the tissues superficial to them. These puffy swellings affect mainly the popliteal spaces, the corresponding parts of the elbows, the anterior aspect of the lower part of each leg, and the regions behind the angles of the jaw, interfering with the movements of these parts, and causing more or less pain and tenderness. Similar extravasations take place especially in the loose connective tissue in and about the eyelids, leading to considerable puffiness and bruise-like discoloration of these parts, and to sanguineous accumulation in the ocular sub-conjunctival tissue. Concurrently with the appearance of these hemorrhages the gums swell at their edges, and rapidly increase in bulk until they form lobulated masses, which rise up around the teeth, and sometimes hide them altogether from view. These masses are spongy, deep red or livid, and insensitive, but apt to bleed; they readily ulcerate or slough, and impart a fetid odour to the breath. The teeth get loose and frequently drop out. The same tendency to ulcerate or slough is manifested in a greater or less degree by all parts of the surface of the body, but especially by those which are the seats of the puffy swellings above adverted to, and by those which present the cicatrices of former injuries. The slightest scratch, pressure, or blow is often sufficient to induce these destructive processes. Along with these phenomena the patient's anæmia increases; his face gets puffy; anasarca takes place in his lower extremities; he becomes breathless; his heart acts rapidly and feebly; and even though retaining, as he probably does, a good deal of muscular strength, he is liable on the slightest exertion, even that of rising in bed, to sudden attacks of syncope, which are attended with the utmost danger to life. During the later periods of the disease, the appetite often fails; the patient suffers from looseness of bowels, the motions frequently being highly offensive, and containing blood, he has disturbance of vision (hemeralopia, nyctalopia), singing in the ears, vertigo, want of sleep, and occasionally delirium. His intellect, however, remains for the most part unaffected. In many cases during the progress of the disease thoracic complications arise, especially effusion into the pleuræ, congestion of the lungs with extravasation of blood into their tissue, congestion of the bronchial tubes, cough, and sanguinolent expectoration, not unfrequently attended with a marked gangrenous odour. The duration of scurvy is uncertain, but it may extend over many weeks or even months. Death is usually due to sudden syncope or gradual asthenia, and may at any time be hastened by the occurrence of hemorrhage, ulceration, thoracic affections, or other complications. Recovery is generally rapid under suitable treatment. But the patient is liable to remain in enfeebled

health, ultimately perhaps to fall a victim to pulmonary phthisis or some other chronic visceral disorder.

*Morbid anatomy.*—The morbid anatomy of scurvy accords with the symptoms of the disease: there is tendency to rapid decomposition; extravasations of blood in various stages of transformation may be found, not only in the superficial regions already specified, but in the substance of the lungs, beneath the pleuræ, in the walls of the heart, in the sub-pericardial tissue, in the intestinal parietes, and beneath the peritoneal membrane. Sanguinolent serum also may be found in the various serous cavities. In other respects the condition of the viscera is very variable. The lungs, liver, and spleen may or may not be congested; the heart may be contracted and empty, or distended with black blood. The brain generally is healthy. The blood contains an excess of fibrine, but presents a diminution in the number of the red corpuscles, and an abnormally low specific gravity.

*Treatment.*—The only effectual treatment of scurvy is the restoration to the dietary of those articles of food to the want of which the disease has been traced—namely, vegetables, and especially those, or those substances extracted from them, which contain citric acid and potash. Among the ordinary articles of diet which are efficacious in this respect must be enumerated potatoes, yams, onions, carrots, turnips, green vegetables of all kinds, inclusive of mustard and cress and scurvy grass; lemons, oranges, limes, grapes, and apples; and, among their derivatives, lemon- and lime-juice and sauerkraut. The provision enforced in emigrant ships, and which has been found effectual in preventing the occurrence of scurvy, is, that each person must have weekly at least eight ounces of preserved potatoes and three ounces of other preserved vegetables (carrots, onions, turnips, celery, or mint), besides pickles, and three ounces of lime-juice. And among the suggestions issued by the Board of Trade to shipowners is the following:—namely, that each man should have at least two ounces of lime- or lemon-juice twice a week, to be increased to an ounce daily if any symptoms of scurvy manifest themselves. The importance of additionally supplying scorbutic patients with good nourishing diet, of taking precautions against sudden syncope, and of relieving by local applications the bleeding ulcerated gums, and ulcers which may exist in other parts, is of course obvious.

---

### XIII. CHRONIC ALCOHOLIC POISONING. (*Alcoholism.*) DELIRIUM TREMENS

Persons who are in the habit of drinking freely fall after a while into ill-health. They lose appetite, suffer from nausea and sickness, have a furred tongue and offensive breath; the limbs become tremulous and enfeebled, the face dull and expressionless, the conjunctivæ congested and watery; an eruption of acne rosacea or acne tuberculata not uncommonly

appears upon the nose and cheeks; they cannot sleep, become low-spirited and vacillating, and lose in some degree both memory and readiness or quickness of apprehension. They are apt to become, also, cowardly, cunning, and untruthful. Further results of drink are: cirrhosis of the liver, which may be followed by ascites, jaundice, or hæmatemesis; affections of the nervous centres, including delirium tremens, epilepsy, mania, dementia, and general paralysis; affections of the peripheral nervous system, causing a special kind of paralysis; and probably also gout and its various consequences. Drinkers (especially, it is said, those who take beer) very often grow exceedingly fat; on the other hand, they not unfrequently get much emaciated. Innumerable material lesions and functional disturbances are, and have been, rightly attributed to the abuse of alcohol; but there is no doubt that, in a very large proportion of cases, the mistake is made of attributing every ailment from which a drinker suffers to the influence of his drink, forgetful of the fact that habits of intemperance, long continued, expose their subject to many dangers, and to be attacked by many diseases, from which he would otherwise probably have escaped.

The parts which principally suffer are the alimentary canal, liver, and nervous centres; but it is to the affections of the last-named organs only that we now propose to direct attention. .

#### *Nervous Disorders. Delirium Tremens*

*Causation.*—Of affections of the nervous centres one of the commonest, and most important, is that commonly known by the name of ‘delirium tremens.’ That delirium tremens, or, as it is sometimes called, ‘delirium e potu,’ is a direct consequence of the abuse of alcohol is beyond dispute. But different views have been held in respect of the mode in which alcohol influences its production. It was long believed to occur only in persons who, after drinking heavily, were suddenly deprived of their accustomed stimulus. More recent inquiries, however, show that it is more commonly the immediate consequence of excessive drinking, and that it usually comes on in the course of long-continued intemperance or of those occasional outbreaks of intemperance (lasting it may be for a few weeks at a time) to which some persons are liable. It may no doubt supervene at the time when such persons are commencing to abstain; but not simply in consequence of their abstinence.

*Symptoms.*—The symptoms of delirium tremens creep on gradually. The patient loses appetite, becomes restless and wakeful at night, his sleep being disturbed by frightful dreams; he grows suspicious, inclined to quarrel, agitated, restless, disposed to busy himself about various matters, and often (as Trousseau observes) to pack up his clothes and prepare for a journey. Generally by the time his disease has become fully established he has had no rest whatever for many nights, and has taken little or no solid food for many days.

The symptoms of the declared affection comprise delirium with hallucinations, and tremulousness of the muscles, together with various more or less characteristic disturbances of the other corporeal functions.

The face is either congested or pale. The pupils usually are dilated, the conjunctivæ injected, the skin bathed in sweat. The tongue varies in character, but in most cases is covered with a thick creamy fur. There is thirst, but the appetite is in complete abeyance. Muscular tremors are almost invariably present; they may be general, or limited mainly to certain parts, such as the head and neck and upper extremities; and they manifest themselves especially when the patient exercises his muscles, but are not necessarily absent at other times; the arms tremble when he holds them out, the legs when he stands, the lips when he speaks, and the tongue when it is protruded. But besides the ordinary trembling, there are often constant fibrillar twitchings of the muscles, which scarcely reveal themselves by causing obvious movement, but may be distinctly felt when the patient's limbs are grasped; and there are often also (but more especially towards the later stage of the disease) involuntary startings of the limbs. The pulse varies: in most cases it does not, in the beginning, exceed the normal, and is then probably large, soft, and diastolic; at a later period, however, and especially if the disease has taken an unfavourable turn, it increases in rapidity (rising it may be to 120 or 140, or more) and becomes at the same time small and extremely feeble. The temperature usually does not exceed  $101^{\circ}$ , and often never rises to that height; but occasionally it runs up more or less rapidly to  $105^{\circ}$ , or even  $108^{\circ}$  or  $109^{\circ}$ . There is no relation between the frequency of the pulse and the elevation of temperature. The mental phenomena are peculiar:—The patient's sleeplessness and tendency to dream are soon attended with hallucinations; he hears noises; he sees black spots, or sparks, or figures; he perceives flavours, or smells smells. His mind begins to wander; he looks suspicious or frightened; he searches behind the bed-curtains, under the bed, or in corners, to satisfy himself that there is nothing there; he becomes garrulous—talking for the most part of business and of projects which he has in hand, but interrupting himself from time to time under the influence of some passing dread, suspicion, or angry feeling. At this time he can be readily recalled to himself, and will answer questions rationally and coherently. The incoherence and delirium, however, soon increase upon him. He now probably is incessantly chattering, talking unconnectedly of things absent and things present, but still with a marked tendency, as a rule, to dwell upon matters of business, to give orders to his servants or workpeople, to talk with customers. He suffers, also, from manifest illusions; he not only has singing and other noises in his ears, but hears voices, and it may be enters into conversation with them; he not only sees muscæ, but takes them (according to their characters) to be insects, or sparks, or coins, and he may be seen endeavouring either to catch the animals which infest him, or to pick up the silver which is strewed around him; or he fancies that he sees dogs or cats, strange persons or devils, and watches them as they slip behind articles of furniture, or peep at him from obscure corners. In many cases his illusions are wholly of a nature to inspire horror or terror; policemen are after

him for some murder he has committed ; he is haunted by bad spirits ; foul reptiles are crawling about him ; great disasters threaten or have already involved his dearest friends. In some cases they are pleasing or funny : he is surrounded by beautiful scenery, he hears sweet music, he sees dancing girls or acrobats performing the most extraordinary feats. In some cases he becomes wildly maniacal ; in some sullen, morose, and stupid. He is apt also to mistake those about him for persons who are absent, or to confound them with the grotesque or horrible creations of his mind. His actions are no doubt in relation with the thoughts or fancies which are passing through his brain ; he will often, as above pointed out, be seen busily picking up insects, flowers, or coins which are crawling or falling about him ; or he will sit up and look suspiciously around ; or he will endeavour to rise from his bed and will hunt everywhere for imaginary objects ; or he will strive to avoid some danger, or some foe, or will attack his attendant in the belief that he is contemplating or perpetrating some injury against himself or his friends ; or he will perform various grotesque acts, such as climbing up the bed-post, standing on his head, or turning head over heels, or will applaud by shouts or laughter some imaginary performance. But in all cases, even though he has well-marked dominant illusions or frames of mind, there is a remarkable changeableness in his illusions and moods ; he passes momentarily from one thing to another, and is suspicious, cowardly, violent, and merry in rapid succession ; and in all cases, or nearly all, he can be recalled momentarily to himself, and restrained by the voice of authority. Epileptiform attacks occasionally come on in the course of the disease.

In most cases, delirium tremens terminates favourably ; and at the end of three or four days, or it may be a week, from the commencement of his malady, the patient falls into a gentle sleep and awakes refreshed and convalescent. But occasionally (and in those persons whose habits insure frequent recurrences, necessarily at length) the attack ends fatally by coma or asthenia. The circumstances which, according to M. Magnan, foretell a fatal issue are elevation of temperature, persistent muscular agitation, and muscular debility or paresis. If the temperature rises to  $102^{\circ}$  or  $103^{\circ}$  (even though other symptoms appear favourable) there is ground for alarm ; if, after continuing at this elevation for a day or two, it suddenly rises above  $104^{\circ}$ , the danger becomes very great and in some degree proportionate to the amount of the rise. As regards muscular tremors, it is not so much their intensity as their general prevalence and persistence which should excite alarm. They are especially of ill omen when they continue during sleep, and when to the general muscular vibration is superadded subsultus tendinum. Great rapidity and extreme feebleness of pulse, epileptic convulsions, coma, and the formation of bed-sores point also to a fatal termination.

The subject of delirium tremens must not be dismissed without drawing attention to the fact that, in persons who are habitual drinkers, it not unfrequently happens that other illnesses (acute or chronic) which attack

them become complicated with the symptoms of delirium tremens. Thus it is with serious accidents, pneumonia, typhoid fever, and other inflammatory and febrile disorders; and thus, also, it not uncommonly is with hysteria. Nor must it be forgotten that delirium tremens is apt to be closely simulated by various affections, and more especially by meningitis and acute inflammations.

Other consequences of drink are epilepsy, insanity in its various forms, general paralysis, and dementia. These, however, are not special to alcoholism, and need not now detain us. Of so-called 'alcoholic paralysis' we shall give a description later on.

*Pathology and morbid anatomy.*—Alcohol taken into the stomach is rapidly absorbed. It is eliminated, but apparently in very minute quantity, by the kidneys, lungs, and skin; yet it disappears quickly from the system. Generally, even if large quantities have been imbibed, none can be detected by chemical analysis after the third or fourth day; but Dr. Dupré believes that ten days may be taken as the period needed for its entire discharge. It is obvious, therefore, that the great bulk must undergo chemical decomposition in the interior of the body. Alcohol may be found post mortem in various organs; it has been discovered in the liver, but is much more readily detected in the brain, for which it seems to have a special affinity. The conditions of the stomach, intestines, and liver, which supervene upon chronic alcoholic poisoning, are elsewhere described. The post-mortem appearances presented by the central nervous organs are not very striking; in those who have long been given to drink, the brain is often found to be shrunken, the subarachnoid tissue opaque, and its proper fluid in excess; but in those who die of delirium tremens, there is usually congestion of the cortex and medulla of the brain, and of the upper part of the spinal cord. Moreover, there is not unfrequently discovered a deposit of refractive granules, and even of hæmatoidine crystals in the walls of the small vessels. There is no reason to believe that other tissues or organs suffer in any important degree. Dr. Dickinson has shown that there are no sufficient grounds for referring chronic renal disease to the effects of alcohol.

*Treatment.*—Our remarks under this head will have reference solely to delirium tremens. It is impossible to reconcile the different views entertained with respect to the treatment of this disorder. Formerly it was held, and by physicians of high eminence and large practical experience, that the one thing needful was to give the patient sleep. But now Drs. Laycock, Gairdner, Wilks, Anstie, and many others, urge that the disease is one of low mortality, which tends to get well of itself within a limited time, and that not only is opium not needed, but its use is attended with no inconsiderable danger. The patient has been without food, or almost without food, for a considerable length of time; and they strongly urge that he should be fed with such nourishment as he can be made to take, and that it is by nourishment mainly that he is to be successfully treated. We do not deny that many of these cases do tend to recovery, and that feeding is an essential point in their treatment; but we cannot help

thinking that more power for harm, and less power for good than it deserves, have latterly been attributed to opium. We think, too, that opiates may be given with more benefit and less danger in inflammatory and other lesions of the brain than is generally suspected. A person suffering from delirium tremens should be separated from other patients; the room in which he is placed should be kept absolutely quiet, and the bright light of day excluded. Everything, indeed, around him should tend to quietude and to solicit sleep. He should be constantly watched by a trustworthy and competent attendant. Under these circumstances it is not generally requisite to employ mechanical restraint; yet sometimes it becomes absolutely necessary to tie him down with a sheet or band, or to fasten his hands or feet to the bed with gauntlets. Nutriment should be administered with careful attention in small quantities and frequently. The most appropriate articles of food are milk, arrowroot, beef-tea, broths, and eggs. The bowels should be regulated. Those who consider sleep indispensable would now administer either chloral or some preparation of opium. The chloral is sometimes given with advantage in doses of from ten to twenty grains every half-hour until sleep is induced. Opium or morphia may also be given in comparatively small doses at short intervals. It is better, however, we believe, to administer it from the beginning in large doses, and to repeat it or not according to its effect; to give, for example, from half a grain to a grain of morphia, or from half a drachm to a drachm of laudanum at once, and to repeat the medicine in smaller doses at intervals of an hour or two, if sleep be not induced. So also with respect to chloral, we believe it better to give a large dose at once, say sixty or eighty grains, and to supplement this with subsequent smaller doses, if needful. If, as is doubtless best, the morphia be given by subcutaneous injection, the dose must be reduced to one-sixth or one-half of a grain. Patients with delirium tremens are difficult to bring under the influence of narcotics. Other remedies which have had, or have, strong advocates, are: digitalis in large doses (half an ounce to an ounce of the tincture); cayenne pepper; and bromide of potassium in doses of from ten to thirty grains. It is sometimes advisable to give the patient some of the alcoholic stimulus to which he has been addicted. When he is convalescent, quinine or other tonics are indicated, and he should, as far as possible, be debarred from drink. The probability, however, is that he will, so soon as opportunity offers, resume his evil habits.

---

#### XIV. CHRONIC LEAD-POISONING. (*Plumbism.*) COLIC. DROPPED HAND

*Causation.*—When lead, in even minute quantities, is habitually introduced into the system, characteristic and serious consequences are pretty certain to ensue sooner or later. In most of such cases the poisoning is very insidious, and not unfrequently its source is only discovered

after patient research or by accident. Plumbism was formerly largely prevalent: in Poitou, in consequence of the habitual addition of lead to inferior qualities of wine; in the West Indies, owing to the fact that leaden worms were used in the stills employed in the manufacture of rum; in Devonshire, as a result of the general employment of lead in the construction of the vessels used in making cider; and, both in our own country and elsewhere, from the storage of drinking-water in leaden cisterns, or its conveyance through leaden pipes. In all these cases, the fluid acting chemically upon the lead, and rendering it soluble, became in a greater or less degree impregnated with it. It is an important fact that rain and other soft waters act much more readily on lead than hard waters, provided these latter contain sulphate and carbonate of lime, and not too large a proportion of alkaline chlorides or nitrates. At the present day the contamination of drinking-water with lead is comparatively rare; and the chief source of lead-poisoning is the employment of this metal in manufacture and trade. To quote the words of Dr. Taylor, 'the carbonate' (to which salt chronic poisoning is usually attributable) 'finds its way into the system, among white-lead manufacturers, either through the skin or through the lungs, or both together; it is diffused through the air as a fine dust, and is not only respired, but taken into the mouth and swallowed with the saliva. It has been remarked that in factories where the powder was ground in a dry state, not only have the labourers suffered, but horses, dogs, and even rats have died from its effects. Since the practice has arisen of grinding the white-lead in water, cases of colica pictonum have not been so numerous. They are still, however, not unfrequent among painters, plumbers, pewterers, the manufacturers of some kinds of glazed cards, the bleachers of Brussels lace, and among those engaged in the glazing of pottery, where oxide of lead is employed in the glaze.' 'The workers in metals—plumbers who handle metallic lead—are but little subject to the disease.' Amongst rare but well-ascertained causes of lead-poisoning are the employment of lead medicinally, its application to ulcerated surfaces (Althaus), the use of snuff impregnated with lead (Hassall and Garrod), the employment of cosmetics containing lead, and sleeping in a newly painted room. Some persons present the symptoms of plumbism who have been exposed in a very slight degree to the poison, who have taken, it may be, only a dose or two of lead medicinally; while others (painters, for example) may go on with their work for twenty years or more, and yet escape.

*Symptoms and progress.*—Those who are under the influence of the chronic operation of lead often suffer in general health; their complexion is said to get sallow and earthy-looking, their skin dry and harsh; they become thirsty, lose appetite, and have a sweetish or metallic taste in the mouth. Dr. Garrod points out a remarkable connection between gout and plumbism, shown by the circumstance that a large proportion (one-fourth) of his hospital gouty patients had suffered from lead-poisoning. And, indeed, whether that connection be accidental, or due to the fact that lead-poisoning predisposes to gout, or that constitutions liable

to gout are also peculiarly susceptible of the influence of lead, general experience confirms the accuracy of Dr. Garrod's observation. Chronic albuminuria is also not unfrequently associated with lead-poisoning. A curious effect of lead was discovered some years ago by Dr. Burton, which is of great importance from a diagnostic point of view: namely, the formation of a blue line along the edges of the gums immediately adjoining the teeth. This is situated in the substance of the gum, but appears to be largely determined by the amount of tartar present, and is supposed to be due to the precipitation of the lead, in the form of the sulphide, by the sulphuretted hydrogen emitted by the decomposing matters which are mingled with the tartar. This blue line is not, however, an infallible sign of lead-poisoning; for it occasionally gets developed in the course of a few hours after the use of two or three medicinal doses of lead; it is generally present in lead-workers who are free from all other symptoms; it often remains long after all possibility of poisoning has passed away; it is sometimes absent from cases of undoubted plumbism; and further, it may be caused by cuprous and other varieties of metallic impregnation. It is said that a similar blue line may be detected at the verge of the anus, and at the margins of ulcers. By far the most important consequences of lead-poisoning, however, are colic, and certain affections (mainly paralytic) of the nervous system. Of these colic is the more common, and, when the two conditions co-exist or alternate, is usually the earlier in making its appearance.

A. *Lead colic* is characterised by the more or less gradual supervention of severe griping pains, attended with obstinate constipation and vomiting. The pains differ in no respect from those which follow upon impermeable intestinal stricture, and apparently are due to the same cause—namely, the powerful contraction, frequently repeated, of certain lengths of bowel above, in order to overcome some impediment to the passage of their contents into and through the length of bowel immediately following. They are referred mainly, as such pains usually are, to the umbilical region, come on at intervals with extreme severity, and, when the disease is fully established, are associated with inter-paroxysmal uneasiness or pain. The pain is not generally aggravated by pressure, and indeed is often relieved both by that means and by friction. The paroxysms are attended with more or less obvious peristaltic movement of the bowels and borborygmi. Vomiting may arise early from sympathy or late from the direct influence of obstruction. The abdominal walls are usually retracted, and the muscles hard and tense. Colic rarely proves fatal; but might readily become fatal if the cause to which it is referrible should continue in operation. Its duration varies; it may last for a day or two only, or be continued for a week, or, with remissions, for a still longer period. Moreover, when once there has been an attack there is great liability to recurrence. It is rarely if ever attended with fever or intestinal inflammation.

B. *Nervous disorders. Dropped hand.*—Of nervous disorders, dropped hand, from paralysis of the extensors of the forearm, is by far the most

frequent ; but sometimes the paralysis is of much more general distribution. Dropped hand generally comes on consecutively to colic, sometimes gradually, sometimes almost suddenly. In some cases one hand only is affected, usually the right ; but more frequently both hands are implicated, though in unequal degrees. The more obvious symptoms of the affection are loss of power over the extensor muscles of the forearm, in consequence of which the patient is unable to extend the hand upon the arm, or the first phalanges of the fingers upon the metacarpal bones, to adduct or abduct the hand, or to abduct the thumb. The hand consequently drops when the arm is held out prone, and both the hand and the first joints of the fingers are flexed in consequence of the predominant action of the flexor muscles. The paralysed muscles waste rapidly, so that a distinct hollow is apt ere long to manifest itself between the bones at the back of the forearm ; they become painful, very tender, and irritable ; and moreover, while retaining their electro-sensibility, they lose more or less completely their faradic contractility, and the tendon reflexes disappear. The remaining muscles of the forearm, and even those of the upper arm, are apt to get enfeebled, though not otherwise affected. There is no impairment of cutaneous sensibility.

The brachial paralysis is limited, as a rule, to muscles supplied by the musculo-spiral nerve, and mainly to those supplied by its posterior interosseous branch. Those which usually suffer are the following, enumerated in the order in which (according to Duchenne) they are liable to be attacked :—extensor communis digitorum, extensor indicis, extensor minimi digiti, extensor secundi internodii pollicis, extensor carpi radialis breviar, extensor carpi radialis longior, extensor carpi ulnaris, extensor ossis metacarpi pollicis, and extensor primi internodii pollicis. Occasionally the muscles of the ball of the thumb suffer, and much more rarely the interossei. But the supinators, and the muscles of the front of the forearm, although they may get enfeebled, seem never to become distinctly paralysed, to lose their faradic contractility, or to waste. It must be borne in mind, however, that the muscles are not necessarily involved in the order above named, and that they do not necessarily all suffer in every case. If the extensor communis be alone affected, only the middle and ring fingers drop, the index and little finger retaining the power of extension, though somewhat enfeebled ; if the extensores indicis and minimi digiti also suffer, all four fingers are implicated ; if the radial and ulnar extensors of the carpus be paralysed, the wrist falls ; if the radial or ulnar alone, then the patient in endeavouring to extend the hand tilts it towards the opposite side ; if the long muscles of the thumb be implicated, the thumb lies in front of the hand in the position of opposition. The power of supination and that of pronation remain intact ; and, provided the first phalanges be supported in the extended posture, the second and third phalanges may generally be voluntarily extended, a fact confirming the integrity of the interossei muscles. The non-involvement of the supinator longus is a fact of much practical importance ; and is best ascertained by placing the patient's forearm mid-

way between pronation and supination, and (while opposing the movement) making him endeavour to bend the arm, when this muscle, which is the flexor of the forearm in this position, starts into high relief.

In some instances the paralysis, loss of faradic contractility, and wasting involve other muscles of the upper extremity besides those of the forearm. Those which are then chiefly liable to suffer are the deltoid and triceps. In some cases the paralysis is limited to the deltoid. Occasionally, again, lead-palsy involves the muscles of the lower extremities, selecting especially the extensors of the foot upon the leg, and of the leg upon the thigh; or the intercostal muscles; or the diaphragm. And in some very rare cases, of which Duchenne quotes a striking example, paralysis attacks almost suddenly nearly all the voluntary muscles.

The duration of saturnine paralysis is very various; it may be weeks, months, or years. Moreover, the paralysis, like the colic, is apt to recur. The longer it has been in existence, the less, as a rule, is the prospect of ultimate recovery; and further, extreme wasting of the muscles, and persistent abeyance of faradic contractility, are also of bad augury. Yet Duchenne draws attention to the interesting fact that in these cases voluntary power may occasionally be recovered, even though the muscles remain irresponsive to faradic excitation.

Epileptic attacks sometimes come on in the course of lead-poisoning, and other cerebral phenomena, including stammering, atrophy of the optic disc, either primary or secondary to optic neuritis, amblyopia or amaurosis, and coma.

*Pathology and morbid anatomy.*—After lead has been received into the organism, it is deposited in various parts, and discharged by various excretories. It has been found post mortem in the spleen, liver, lungs, kidneys, heart, and intestinal walls, and also in the substance of the brain and in the muscles. It passes off mainly with the urine; but, according to Dr. Pereira and others, there is some elimination by the skin; and Dr. Taylor states that it has been found in the milk. It is apt to remain in the tissues for some time, and has been detected in them by M. L. Orfila as long as eight months after its reception has been discontinued. The appearances found after death from chronic poisoning are for the most part very indecisive. After death from colic, or in cases in which colic has been present, the bowels (especially the large intestines) are said to be generally contracted and empty, or to present alternate contractions and dilatations, or intussusceptions; occasionally, also, spots of congestion have been seen in the mucous membrane. These are changes, however, which may be observed in many cases besides those of lead-poisoning. The paralysed muscles, as has been already stated, shrink rapidly and to an extreme degree; and post mortem are often observed to be remarkably pale and yellowish. But, on microscopic examination, their tissue is usually found to present a perfectly normal appearance. It is only after paralysis has existed for many years that degenerative changes are added to simple atrophy. The fibres sometimes become fatty. Whether the

intestines are affected through the nervous system, or by the presence of lead in their walls, may be a subject of doubt. But, as regards the paralysis of the voluntary muscles, there is no doubt that Duchenne is right in regarding it as a consequence of nervous disorder. For if it were muscular, not only should we find the muscular fibres degenerated in proportion to their loss of power, but we should find faradic contractility surviving as long as any healthy muscle was left. On the other hand, the rapid shrinking of the muscles, without degeneration, and their speedy loss of faradic contractility obviously point to lesion either of the nerve-trunks or of their nuclei of origin.

*Treatment.*—Whenever a case of lead-poisoning comes under treatment, a careful inquiry should be made into the probable source of contamination, with the object of removing or counteracting it, or of putting the patient upon his guard. It is obvious that it would be well for patients whose occupations expose them to the danger of continued lead-poisoning to seek some other employment. But this they will rarely consent to; and, indeed, it is often impossible for them to do it. Apart from the question of the improvement of processes of manufacture in order to minimise the risks of those employed (a subject upon which we do not presume to enter), it may be mentioned: that extreme personal cleanliness is important for all those who are exposed to danger; and that there are good grounds for believing that the habitual use of lemonade made with sulphuric acid is to a considerable extent protective, by converting the carbonate or other salts of lead in the stomach into the insoluble and inert sulphate.

Various methods of treatment have been suggested with the object of removing lead from the system—the more important of them being the employment of baths containing some soluble sulphide, and the internal use of iodide of potassium. Pereira recommends baths medicated with sulphide of potassium, in the proportion of two ounces to fifteen gallons, in the belief that the lead escaping from the surface of the skin would thereby be converted into the insoluble sulphide. This result does in fact happen; but there is no reason whatever for supposing that the baths promote the escape of lead in any important degree. M. Melsens suggested the employment of iodide of potassium, on the ground that the iodide makes, with the insoluble salts of lead deposited in the tissues, a soluble double salt capable of removal by the kidneys. This practice is commonly followed.

In the treatment of lead-colic it is best, we believe, to relieve pain and discomfort by opiates and fomentations, and to leave the bowels to act of themselves, as they will usually do at the end of a few days. If it be thought right to remove the contents of the lower bowel, this may be effected by means of copious enemata of warm water or warm gruel. Many, however, prefer the course which Sir Thomas Watson advocates; namely, the exhibition of a full dose of calomel and opium (ten grains of the former with two of the latter), which he says usually soothes the vomiting, restlessness, and pain, and may be followed up successfully by

a dose of neutral salts or castor oil. Alum, in doses of a scruple or half a drachm three times a day, has been highly recommended.

For the restoration of the paralysed and wasting muscles, galvanism is the only effectual remedy. Faradism is employed by Duchenne, who recommends that a powerful current should be used three times a week for as long a period as may be necessary—it may be as much as two or three months. Each sitting may last for ten or fifteen minutes. He recommends, also, that each muscle should be separately galvanised. The slowly interrupted constant current, similarly employed, is even more efficacious.

---

## XV. CHRONIC MERCURIAL POISONING. (*Mercurialism*)

*Causation.*—Chronic mercurial poisoning may result from the long-continued medicinal use of any of the preparations of mercury; but it is most frequently due to habitual exposure to the vapour or dust of mercury or its salts, which certain manufactures or trades involve. Those, therefore, who chiefly suffer are the workmen engaged in quicksilver mines; water-gilders; the manufacturers of looking-glasses, barometers, and thermometers; furriers, and those engaged in the packing of furs which have been brushed over with solution of nitrate of mercury.

*Symptoms and progress.*—The symptoms of chronic mercurial poisoning have reference mainly to the nervous and muscular systems, and are commonly included under the term ‘metallic tremor.’ The first indications of this condition are: a general tremulousness of the hands and arms, coming on for the most part gradually; slight numbness or tingling in the hands or feet; and occasional pains in certain joints, more especially those of the thumbs, elbows, feet, and knees. Tremors are common amongst workpeople exposed to the vapour of mercury, and may continue for years without materially interfering with their capacity for work or their general health. But sooner or later they tend to get aggravated; they not only become more violent, but gradually extend to all parts of the muscular system; so that they involve at length the hands, arms, and legs, the head and neck, including the muscles of expression, speech, and deglutition, and the trunk with the muscles of respiration. Then the violent trembling of the hands and arms renders the patient more or less incapable of using them for any purpose, especially for delicate operations—he probably cannot lift a glass of water to his lips, or feed or dress himself; the agitation of his legs gives to his attempts to walk or stand a peculiar jerkiness or choreic character, and, indeed, before long he is probably unable to stand or walk without support; the convulsive action of the muscles of his head and neck causes constant tremulous movements of these parts, while that of the muscles of expression reveals itself in grimaces, and that of the lips, tongue, and muscles of mastication causes tremulous, indistinct, and divided utterance, and difficulty of mastication; the involvement of the respiratory muscles induces difficulty of

breathing. All these convulsive movements are usually in abeyance when the patient is lying down and making no muscular effort; but they reveal themselves whenever he attempts voluntary movement, and become especially aggravated whenever he is under observation. Further, the patient is liable to occasional, apparently causeless, exacerbations. At a very advanced period of the disease, the convulsions do not wholly cease when the patient is in bed, and occasionally also continue during sleep. Moreover, they are now not unfrequently associated with sharp pains in the limbs, and occasional attacks of tonic contraction. It would seem (and the point is an important one) that the muscles of the eyeballs do not share in the convulsive movements, and that there is an absence of nystagmus. There is no real loss of sensation.

The symptoms above enumerated are not necessarily associated with any other indications of mercurial poisoning or signs of ill-health. But in a considerable number of cases the patients either have previously suffered from salivation and ulceration of the gums, fetid breath, nausea, sickness, colicky pains, disturbance of the bowels, and fever; or present these phenomena at the time when the nervous symptoms supervene; or begin to suffer from them during the course of the tremors, even if they have never thus suffered previously. And generally, after the tremors have attained a high degree of severity, cachectic symptoms come on; the patient gets sallow, emaciated, and weak; he loses appetite; and there is general failure of his circulatory and other functions. Sometimes, also, cerebral complications are developed, such as vertigo, headache, loss of memory, delirium, epilepsy, paralysis, or coma.

Chronic mercurialism is not generally a fatal or even dangerous disease; mainly for the reason that those who are affected with it are usually compelled to give up their employment, and thus escape further risk. Under such circumstances restoration to health may often, with proper treatment, be effected in a few weeks or months. In aggravated cases, however, the tremors may continue for years, occasionally presenting a remittent character, dependent apparently on accidental conditions of health. But for such as continue to expose themselves to the vapour of mercury, the prospect of early death is by no means uncertain—death under such circumstances being caused either by extreme debility, or by some of the ordinary effects of mercury on the gums and mouth, or intestinal canal, or by some cerebral complication, or by the supervention of intercurrent disorders.

The affections with which mercurial tremors are most likely to be confounded are disseminated sclerosis, and paralysis agitans. But careful attention to the history and details of symptoms will generally enable an accurate differential diagnosis to be made between them. It may, however, be pointed out, as practical hints, that paralysis agitans does not commonly affect the muscles of the head and neck, but imparts to the patient a tendency to run forwards, and that generally in disseminated sclerosis there is well-marked nystagmus.

*Morbid anatomy.*—No characteristic lesions have been discovered in

the internal organs of patients who have died of chronic mercurialism. But mercury has been detected chemically in various parts of the body, more especially the brain, liver, and kidneys.

*Treatment.*—The preventive treatment of mercurial poisoning includes the taking of measures to guard against the entry of mercury into the system, either by adopting such modifications of the processes of manufacture as minimise the diffusion of the poison through the atmosphere, or by compelling the workers to wear respirators or other protective coverings to the face, to wash their hands before eating, and to change their clothes and wash after leaving work. The direct treatment of chronic mercurialism by drugs is of little use. It may on the whole be judicious to act on the bowels, kidneys, and skin, for the purpose of promoting the discharge of the poison. It may even be well to adopt the treatment already suggested for chronic lead-poisoning, namely, the administration of iodide of potassium, with the object of combining the mercury in the system therewith into a soluble double salt. But the essential part of the treatment, and that which is alone of real efficacy, is the removal of the patient from the influence of mercury. Tonics may often be given with advantage to the patient's general health; and galvanism may be applied with benefit to the enfeebled muscles.

## CHAP. V.—DISEASES OF THE DIGESTIVE ORGANS

## SECTION I.—DISEASES OF THE MOUTH, FAUCES, AND ADJACENT PARTS

## I. CATARRH

*Causation.*—The most common, and on the whole perhaps the most important, variety of inflammation affecting the mouth, fauces, and parts in relation with them, is that which results from exposure to cold, and gives rise to the phenomena which collectively constitute what is commonly known as a ‘cold’ or ‘catarrh.’

*Morbid Anatomy.*—Catarrhal inflammation commences with hyperæmia, infiltration, and tumefaction of the affected mucous tissue, diminution of the secretions from its surface, and from the glands which open upon it, and consequent abnormal dryness. Before long, however, the inflamed parts begin to pour out a thin, watery, somewhat acrid discharge, in considerable abundance; and at the same time the tumefaction usually undergoes some diminution. Subsequently the secretion gets thick, opaque, and yellowish or greenish, and assumes the characters of muco-pus or pus. This change generally indicates the commencement of the end; for now, if nothing occurs to interfere with the normal progress of the case, the tumefaction and secretion both gradually subside, and the mucous membrane returns to its healthy state. Catarrhal inflammation does not, as a rule, seize at once on any extensive tract, but rather, like erysipelas, begins in a comparatively small area, whence it spreads. Nor does it, even in the case of anyone who is liable to it, always commence in the same spot. Thus it often, perhaps most frequently, begins in the mucous membrane of the nose, whence it spreads by continuity to the fauces, and thence to the larynx and probably to the trachea and bronchial tubes; or it first manifests itself in the larynx, whence it extends upwards into the nose, and downwards into the chest; or it first attacks the fauces, soft palate, or it may be the gums. The regions which are liable to be involved in the course of catarrh, and in any one of which probably it may commence (thence extending to the others), are the following:—the nose and sinuses in relation with it, with the lacrymal ducts and conjunctivæ; the fauces and pharynx, together with the Eustachian tubes and tympanic cavities, and the œsophagus; the oral cavity, including the palate, gums, sockets of the teeth, and tongue; the periosteum of the facial bones, and branches of the fifth pair; and lastly, the larynx and subordinate respiratory passages.

*Symptoms and progress.*—The symptoms of a cold necessarily differ

according to the regions which mainly suffer. The special symptoms, however, are always associated with the ordinary phenomena of febrile disturbance. The latter vary in severity, but are generally mild (sometimes scarcely noticeable) and always most severe during the first day or two of the attack. They comprise elevation of temperature, heat and dryness of skin alternating with perspirations which come on mainly at night time, increased frequency of pulse, thirst, constipation, scanty urine with abundant uratic deposit, muscular pains, and frequently drowsiness. The febrile symptoms are sometimes alarming in the case of young children.

The symptoms of catarrh affecting the cavity of the nose are in the first instance dryness, obstruction, and irritability of the nasal passages, associated with frequent paroxysms of sneezing, the performance of respiration mainly through the open mouth, and inability to pronounce the nasal consonants, *m*, *n*, and *ng*. To these succeeds defluxion of thin watery mucus, which frets the margins of the nostrils and the upper lip. There is probably still great irritability of the mucous surface, with paroxysmal sneezing; but with the continuance of the discharge the nasal passages become more pervious, and the symptoms due to obstruction to some extent subside. Finally, the discharge gets thick, and at the same time less abundant, the tumefaction and irritability of the mucous membrane diminish, and convalescence ensues. Associated with nasal catarrh there is always loss of smell, especially during the earlier stages; and, probably owing to implication of the frontal sinuses, there is often severe headache, limited to the situation which the sinuses occupy, and not unfrequently attended with drowsiness. The extension of inflammation to the conjunctivæ is shown partly by obstruction of the lacrymal ducts, in consequence of which the tears are compelled to flow over the face, partly by the supervention of ophthalmia.

The indications of catarrhal inflammation of the fauces are: unnatural redness of the soft palate and pillars of the fauces, and, in a greater or less degree, of the contiguous mucous surfaces; and tumefaction of the same parts, but more particularly perhaps of the lax tissue of the uvula, which is apt to become œdematous and enlarged in all its dimensions. The first symptoms of which the patient complains are dryness, stiffness, and itching or tingling, commencing at one side, or in some defined area, but soon becoming more or less general throughout the fauces and soft palate, and frequent tendency to swallow in order to relieve the uncomfortable feeling in the throat, and to cough a slight hacking cough. The act of deglutition is more or less painful. With the supervention of the stage of secretion, the efforts to swallow and clear the throat get more effective and freer from pain, the patient becomes comparatively comfortable, and convalescence soon follows. Involvement of the Eustachian tube and ear is indicated, first by itching or shooting pains in the course of the tube and in the ear, then by deafness and the usual signs of aural inflammation. Extension of catarrh along the œsophagus to the stomach is rarely if ever manifested by prominent symptoms. Those usually observable are a sen-

sation of warmth along the œsophagus and in the stomach, and slight dyspeptic symptoms, more especially frequent eructations and craving for food.

Catarrhal inflammation of the mouth more frequently and seriously affects those who suffer from bad teeth than those whose teeth are sound, and reveals itself mainly by pain, tenderness, and swelling of the gums, and particularly of the periosteum of the sockets of the teeth. The teeth consequently become loose and tender; and neuralgic pains, often most severe at night-time, flicker about the gums, and sometimes extend to the periosteum of the jaws, and along the superficial branches of the fifth pair.

Catarrhal inflammation of the larynx is elsewhere described under the name of laryngitis, and that of the bronchial tubes under the name of bronchitis.

It remains to say that catarrh, in the sense in which the word is employed in the present article, is an affection of very various importance. In the majority of cases it must be regarded as a trivial disorder, which reaches its full development in the course of a day or two, and lasts at the outside not more than a week or ten days. Yet, without attaining any special severity, it may be kept up for an almost indefinite period if the patient continue to expose himself to its exciting cause. Nor can it be regarded as entirely devoid of danger, especially if it involve the larynx or bronchial tubes; for, although in many cases the laryngeal or bronchial affection is really slight, it differs only in degree from the severest forms of primary laryngitis or bronchitis, and may readily pass into one or other of them. Further, although the pain and discomfort of catarrh are commonly neither severe nor of long duration, there are exceptions to both of these rules. The chief exceptions are furnished by those cases in which the inflammation spreads to the teeth, periosteum, and branches of the fifth pair, and those in which it attacks the ear—in both of which cases the pain is often intense, and continues maybe, with little intermission, for weeks or months.

*Treatment.*—Trivial as a common cold may seem to be, it is yet of such frequent occurrence, and a source of so much discomfort, especially to those who are liable to its attacks, that its treatment cannot be regarded as unimportant. As a general rule patients suffering from cold should confine themselves to a warm and well-ventilated but not draughty room; and should, if not in bed, be warmly clad. A hot bath (water, vapour, or air) should be taken before going to bed, together with some warm drink, and a little Dover's powder—measures which are serviceable in relieving pain and discomfort, in promoting sleep, and in exciting perspiration. During the day the occasional inhalation of steam is often useful, as also are frequently repeated small doses of ipecacuanha and opium, either in the form of Dover's powder, or associated with some febrifuge mixture, or with ether or ammonia. Sir T. Watson notices with especial approval the treatment of a commencing catarrh with (in the adult) about twenty minims of laudanum at one dose, or with about half

that quantity of laudanum combined with seven or eight minims of vinum antimoniale, repeated every third or fourth hour for three or four times ; as also Sir Henry Hallford's practice (which accords pretty nearly with the usual domestic routine) of giving at bedtime a beaker of hot wine negus with a tablespoonful of the syrup of poppies. He also observes that there is 'a period in catarrh which has gone on unchecked when you may accelerate its departure by a good dinner and an extra glass or two of wine.' Counter-irritation is sometimes serviceable ; and, if the fauces or larynx be dry and uncomfortable, the frequent sipping of warm milk, barley-water, gruel, or 'treacle posset,' or the use of black-currant jelly, or such like things, is often a source of considerable comfort. Sucking ice in many cases answers the same purpose. In the latter stages of faucial catarrh, or when the affection has become chronic, astringent applications, in the form either of gargles, or of spray by means of the atomiser, may be useful. Occasionally, but for the most part as the result of repeated catarrhal attacks, the uvula gets elongated, and is believed to irritate the larynx, with which it comes in contact. Under such circumstances the tip may be readily and safely snipped off with scissors.

It is very desirable to obviate, if possible, the liability to catarrh which so many persons labour under. There is no doubt that active exercise in the open air, and all other habits which tend to promote good health, tend also to diminish this liability ; and many a person will in his autumnal holiday expose himself with impunity to conditions which at home would certainly have brought on a severe attack. So far as possible, therefore, exercise and other health-conducive practices should be enjoined. It is not, however, the exposure which attends active exercise that as a rule induces cold, unless, indeed, the patient has undergone great fatigue, and consequently fails to keep himself warm ; but it is rather the exposure when one is still, especially when one is still after previous violent exertion and exposed to a cool breeze, to a cool draught of air, or to the coldness induced by wet clothes or the evaporation of sensible sweat. The means of obviating such dangers are too obvious to need enumeration. It is generally held, and we believe with reason, that a matutinal cold bath followed by friction with a rough towel, and then by walking or other exercise, is a good preventive of colds. The shower-bath has been especially recommended for this purpose. It is, nevertheless, a fact that the continued use of the shower-bath will in some persons, so far from obviating the liability to cold, induce it, and keep up a permanent catarrhal state.

## II. THRUSH. (*Aphthæ*)

*Causation and morbid anatomy.*—Inflammatory affections of the mouth and fauces frequently arise in connection with stomach and bowel disturbance—sometimes simultaneously with it, sometimes secondarily to it, and more rarely, perhaps, as the first step in the order of events. Such inflammations are sometimes catarrhal in the anatomical sense of the word, and

hence not readily distinguishable in all cases from the effects of ordinary cold. They do not, however, so far as we know, tend, as the latter variety does, to involve the nasal cavity and air-passages, or to extend to the eye, ear, sockets of the teeth, or branches of the fifth pair; while, on the other hand, they involve the mucous membrane of the mouth much more prominently.

Thrush is characterised for the most part by the appearance in greater or less abundance, on the tongue, gums and palate, inside the lips and cheeks, on the soft palate, and pillars of the fauces, and even on the surface of the pharynx, of small, elevated, opaque, whitish spots, which are round or irregular in form, pretty firmly adherent, and not unfrequently appear like attached flakes of curdled milk. These can be easily separated, leaving more or less distinctly excoriated areas or ulcers behind.

In its best marked form it presents a very characteristic appearance. It begins with the formation of minute white rounded elevations, which

gradually increase in size until individually they attain perhaps the bulk of a mustard-seed or tare. These are hemispherical in form, adherent by broad bases, smooth on the surface, and uniformly solid; and like the former variety are scattered irregularly, sometimes sparsely, sometimes in great abundance, over the surfaces above enumerated.

FIG. 57.—*Oidium albicans*.  $\times 500$ .

Under the microscope aphthæ are found to consist of a cryptogamic plant, called the *oidium albicans*, the mycelium of which infiltrates the subjacent epithelium. The source of this parasite has not been clearly ascertained, but Hallier regards it as identical with the *oidium lactis*. If this be

so, the explanation of its occurrence in infants at the breast, and in persons wasted with disease, is not far to seek.

*Symptoms and progress.*—Aphthæ are common in young children, more particularly infants at the breast; but are frequent also both in children and in adults in the course of many diseases, especially when they are attended with hectic fever or the typhoid state. In young children thrush is generally preceded by and attended with feverish symptoms (heat of skin, fretfulness, and drowsiness), diarrhœa, or other morbid conditions of the bowels, loss of appetite, vomiting, and unwillingness to take food. Gastro-intestinal disturbance, indeed, is rarely absent; and it is believed by many that aphthæ of the mouth indicate a similar con-

dition of the stomach and alimentary canal. The lips usually are dry, and the tongue, especially at the tip and edges, redder and drier than natural, and with a tendency to get furred on the dorsum and towards the base. The anus and its vicinity in such cases are sometimes reddened and excoriated, and aphthæ have been described as existing there. Aphthæ may subside after a few days, or last continuously or with remissions for many weeks. Thrush is not in itself dangerous, or necessarily an indication of danger in the affection which it attends. It must not be forgotten, however, that it frequently accompanies gastro-intestinal lesions which prove fatal, and that its presence cannot but add something to the danger of an already dangerous disease. When thrush supervenes in the course of diseases affecting adults, although it is not necessarily an indication of impending death, it is yet often a symptom of grave omen.

*Treatment.*—In the treatment of thrush it is important in the first place to attend to the general health, and especially to the condition of the alimentary canal. In children it is generally best to commence the treatment with a dose of castor oil, or of rhubarb in combination with carbonate of magnesia or grey powder, and then to administer medicines calculated to improve the tone of the stomach and bowels. According to the particular symptoms present may be prescribed lime-water with milk, small doses of rhubarb with ginger or some other aromatic, aromatic confection with chalk and opium, or vegetable bitters. Locally, relief may be given by the application of borax combined with glycerine or honey, or solution of tannin, sulphate of zinc, or nitrate of silver; by washing out the mouth with a solution of chlorate of potash; by rinsing it with mucilaginous fluids; or by the use of lozenges containing gelatine or mucilage. With the object of destroying the parasite, solution of sulphurous acid has been recommended.

---

### III. STOMATITIS

#### A. *Simple Ulcerative Stomatitis*

*Causation, symptoms, and progress.*—It is common, both during infancy and in adult life, for small ulcers to appear on the mucous membrane of the lips, cheeks, and tongue. These commence as small vesicular elevations, which speedily undergo excoriation, and become converted into shallow, circular, yellowish or ashy ulcers, surrounded each by a rim of more or less intense congestion. They are often solitary, and generally disappear in the course of a few days, but are apt to be very sore and painful, and to occasion much discomfort during their continuance.

In many cases—mainly, we believe, in adults—such ulcers occur in crops, or follow one another in irregular succession for weeks or months at a time, causing great and continuous misery, and interfering

seriously with the digestion of food, and consequently with the patient's nutrition.

Occasionally the liability to their occurrence continues for years, and maybe for the patient's lifetime. In such cases there are, generally, periods, of irregular duration, in which the sufferer is wholly free from his disease. But now and then the affection becomes persistent, and by its persistency and the abundance of the small ulcers, their individual intractability, and the amount of congestion and thickening of the intermediate tracts of mucous membrane, causes so much local and constitutional disturbance, and so much impediment to the introduction of food, that the patient finally sinks from sheer exhaustion. In such cases the ulcers seem to arise indifferently in all the situations above specified; but their favourite seats would seem to be the lips, especially where these become continuous with the gums, and the angles of the mouth.

Whether the above varieties of stomatitis are all of the same nature is open to doubt; but the individual ulcers which characterise them are undistinguishable in their origin, progress, and anatomy. Their causation is also doubtful. The solitary ulcers occur, for the most part, in persons otherwise healthy. In some of the more aggravated and protracted cases the stomatitis occurs in association with derangement of the digestive functions, and possibly may be due to this derangement. We are disposed, however, to believe that the grave and intractable forms of the disease come on mainly, if not exclusively, in the course of protracted anæmia (probably pernicious anæmia), and that their gravity and fatal tendency are largely due to this circumstance. It may be added that patients who are liable to outbreaks of simple ulcerative stomatitis can often foretell the occurrence of an outbreak by the coming on of a sense of diffused heat and tingling in the mouth.

*Treatment.*—For the treatment of casual ulcers in the mouth, the application of nitrate of silver or sulphate of copper to the individual ulcers is usually sufficient. Honey or glycerine of borax, or solution of chlorate of potash, may also be of service.

In the more severe cases, similar local treatment may be resorted to; but for the purposes of cleansing the mouth, of relieving pain, as well as of cure, solutions of cocaine, of quinine, of chlorinated soda, or of other sedatives or cleansing preparations, may be needed. In these cases, however, good nourishment and constitutional remedies are specially indicated. Amongst the latter may be included stomachics, quinine, iron and other tonics, and arsenic.

### B. *Acute Ulcerative Stomatitis*

*Causation and morbid anatomy.*—A peculiar affection of the mucous surface of the cavity of the mouth is sometimes met with, chiefly if not entirely in children below the age of puberty, which has a close relation, at all events anatomically, to that observed in cattle affected with the foot-and-mouth disease. It is impossible to deny that there is also some

resemblance between this affection and both thrush and the early stage of gangrenous ulceration. Yet the appearances are so peculiar, and the whole progress of the affection so like that of a specific disease, that there is good reason to regard it as an affection *sui generis*. It consists in the formation of excoriated patches, chiefly limited to the surface of the gums, and corresponding parts of the cheeks, but occurring also on the dorsum and sides of the tongue, mainly towards the base, on the palate, and on the general surface of the buccal mucous membrane. The excoriations vary in size and shape, but are mostly irregular and tending to run together; their surface is raw, red, and weeping, sometimes bleeding; and the surface of the mucous membrane between them is thickened and opaque. The tongue (excepting the spots of excoriation) is generally covered with a thick, tough, opaque, whitish fur, and its surface looks not unlike a piece of wash-leather.

*Symptoms and progress.*—The approach of the malady is usually indicated by some degree of feverishness and malaise—symptoms, indeed, differing little if at all from those that usher in an ordinary cold. Then, after a day or two, some soreness is experienced in masticating, speaking, and deglutition; and if the mouth be examined, the morbid phenomena above described will be recognised in an early stage. The progress of the affection is attended with febrile symptoms—heat of skin, flushing of face, listlessness, drowsiness, thirst, loss of appetite, and the like. And these, together with the local phenomena, usually subside in the course of a week or ten days. In some cases the affection of the mouth assumes a more chronic character. We are not aware that it ever leads to serious consequences.

*Treatment.*—For local treatment mel boracis, or chlorate of potash in solution, seems to be indicated. Internally, a little chlorate of potash or other febrifuge medicine may be administered.

#### IV. NOMA (*Gangrenous Stomatitis*). GANGRENE OF FAUCES

##### A. Noma

*Causation.*—Gangrenous ulceration of the mouth occurs almost exclusively in children under twelve years old, and indeed is mainly limited to those whose ages lie between one and five. Its cause is not very obvious. There is no doubt, however, that it is especially apt to become developed during convalescence from acute febrile disorders, among which measles stands pre-eminent, and in children who have been badly fed or are anæmic.

*Morbid anatomy.*—The gangrene may commence at any part of the buccal surface, and in several parts at one time. But it usually originates in the sulci between the gums and cheeks, and chiefly (according to Barthez and Rilliet) in that connected with the lower jaw. It begins variously: sometimes with ulceration or the formation of a superficial

slough; sometimes with congestion, thickening, and tension of the substance of the cheek or other soft parts circumscribing the oral cavity. In any case there soon appears on some part of the mucous surface of the mouth an irregular greyish or black sloughy patch surrounded with a rim of intense and somewhat livid congestion. This tends to spread rapidly both in area and in depth—its extension being preceded and accompanied by infiltration, hardening, and congestion of the tissues. The cheek in the affected neighbourhood frequently becomes tense, shining, and livid. With the extension of the gangrene, the gums may be eaten away, the alveoli necrosed, and, if the patient live sufficiently long, the teeth and portions of the jaw may exfoliate, and the soft palate, fauces, and tongue, each and all, be more or less extensively destroyed. Very frequently the cheek gets perforated; and the destructive process may then spread almost indefinitely, involving in turn the mouth, the entire cheek, and it may be the nose, the eye, and other contiguous parts.

*Symptoms and progress.*—The symptoms which attend noma are, at all events in many cases, much less severe than one would expect them to be. It often happens that the gangrene has made some progress in the interior of the mouth before anything has occurred to call special attention to what is going on there; and, indeed, it is not a rare thing to find patients in whom gangrene has committed the most extensive and frightful ravages, and for whom recovery is hopeless, who neither suffer pain nor have suffered it, who maintain a good appetite, and continue sensible and even cheerful. The special symptoms, in addition to swelling of the cheek and the actual progress of the gangrene (which is obvious enough if looked for), are: more or less profuse salivation, the discharge often being bloody and foul; extreme fetor of this discharge and of the breath; and swelling of the neighbouring lymphatic glands. As above indicated, the patient often suffers very little pain or uneasiness, remains sensible, talks, and takes an interest in whatever is going on about him, and retains his desire for food and the power of taking it. But notwithstanding this, the pulse rises in frequency and gets small and feeble; the surface grows pale and cold; drowsiness or delirium comes on; diarrhoea perhaps sets in; and death from asthenia supervenes at the end of a few days. In a small proportion of cases recovery takes place, with more or less deformity.

### B. Gangrene of Fauces

*Causation.*—But gangrene, not specially limited in this case to young children, may commence in the fauces or pharynx. In some cases this is due to diphtheria or scarlet fever, or results from the mere intensity of the inflammation in ordinary tonsillitis. But it may also occur independently of such special diseases, and, like noma, be traceable to profound impairment of the general health.

*Symptoms and progress.*—The symptoms in these several cases differ in some degree according to the nature of the disease to which the gangrene is due. Eliminating, however, the symptoms referrible to the

several specific affections which have been named, gangrene of the fauces would be revealed by tumefaction of the tissues, the appearance of sloughs upon the surface, fetid discharge and breath, swelling of the glands beneath and behind the jaw, and, in addition to these phenomena, difficulty and pain in deglutition, and probably, before long, difficulty of respiration. The situation of the morbid process necessitates the presence of much more pain and discomfort than are usually associated with noma; and here, as in the other case, very extensive destruction of tissue may take place, and perforation ensue. The general symptoms are: feebleness of pulse, sometimes with quickening, sometimes with marked diminution of frequency; pallor; coldness of surface; tendency to collapse; and not unfrequently, before death, copious perspirations, diarrhœa, and impairment of consciousness, delirium or coma.

### *C. Treatment*

In treating gangrenous affections of the mouth and throat, it is in the first place of paramount importance that the patient's strength should be maintained by the regulated administration of nutritious food and alcohol, and of tonic medicines, or these combined with diffusible stimulants. Opium here, as in all similar cases, may be of great service. For local treatment, it is necessary to keep the parts cleansed; to wash them frequently with antiseptic fluids, such as solutions of chlorinated soda, chlorine, hydrochloric acid, permanganate of potash, or chlorate of potash; and to treat the gangrenous tracts themselves freely with escharotics, of which probably the most valuable are pure hydrochloric or nitric acid, and the actual cautery.

---

## V. INFLAMMATION OF THE GUMS IN DENTITION

Cutting the teeth is always attended with discomfort, if not absolute pain. Previous to the actual eruption the implicated gum generally becomes congested, swollen and tense, and often distinctly inflamed. Occasionally suppuration or ulceration takes place. The eruption of the second teeth is seldom attended with symptoms which call for the notice of the physician. The eruption of the first set, however, is a fertile source of infantile ailments. This is especially the case when it occurs early. It is well known to mothers and nurses that infants who are on the eve of cutting their teeth begin to dribble and to bite the finger or any other hard substance which may be introduced into the mouth; and, looking upon these symptoms as an indication for treatment, they give the babe an ivory or india-rubber ring or a piece of coral to bite.

So far the symptoms may be regarded as normal; but in many cases the congestion of the gum produces feverishness and fretfulness, interferes with the infant's rest, and induces sickness and diarrhœa. When these phenomena ensue, each may be treated according to its importance: the

vomiting may be allayed by the exhibition of some aromatic, or the addition of a small quantity of lime-water to the milk; the diarrhoea may be rectified by the administration of a little castor oil or Gregory's powder, followed, if necessary, by a little aromatic confection and chalk; the restlessness may be met by minute doses of opium. In the great majority of cases, however, the most efficacious and the best treatment is freely to lance the inflamed gum.

In some instances convulsions are referrible to the irritation of the emerging teeth. Under such circumstances, in addition to the appropriate treatment for convulsions, lancing of the gums must be efficiently performed.

Many other maladies besides the above are commonly regarded as consequences of dentition, the principal of them being eczema, lichen, and impetigo in various forms, bronchitic affections, and paralysis. It is doubtful, however, whether dentition has any other effect upon them than that of aggravating them.

---

## VI. GLOSSITIS

*Causation.*—Besides the superficial forms of inflammation in which the tongue shares with the other parts bounding the oral cavity, the organ is liable to become inflamed throughout its whole substance. This occurrence, which is rare, may take place under the influence of the mercurial poison, or as a consequence of direct injury, but now and then arises independently of all such obvious causes.

*Symptoms and progress.*—Idiopathic glossitis is said to be preceded in some cases by premonitory febrile symptoms. In other cases the inflammation is certainly, so far as one can judge, primary, although attended probably from the commencement with febrile disturbance, and even with rigors. It sometimes commences in the tongue itself, at other times in neighbouring parts, especially the fauces. The tongue then becomes swollen, stiff, and painful, and incapable of executing its proper functions. The swelling is usually general, although sometimes limited to one half, or it may be some lesser portion. In the first case the organ gets enlarged in all its dimensions, sometimes so thick as to render inspection of the back of the mouth out of the question, so wide as to project on either side between the molar teeth, so long as to protrude beyond the lips, and even exerting serious pressure upon the upper part of the larynx. The pain is usually of a throbbing or burning character, and increased by all attempts at movement, so that mastication, deglutition, and articulation are in some cases almost impossible. Saliva accumulates in the mouth, and the patient's sufferings consequently become much aggravated. The surface of the tongue may in the first instance be redder than natural, but very soon gets enveloped in a thick white creamy fur. Occasionally suppuration takes place and an abscess forms. The affection usually attains its height in the course of three or

four days, and, if free from complication, subsides in the course of a week or ten days. Permanent hypertrophy of the tongue has sometimes resulted.

The sufferings of a patient with glossitis are usually out of proportion to his danger. Some of them have already been referred to; but one of the most serious is the sense of impending suffocation which is often present, and which alone may be sufficient to prevent all sleep and forbid even temporary ease. It is quite possible, however, that from extension of œdema or inflammation to the larynx dangerous symptoms, and even death, may ensue. The disease, therefore, is one which needs close and careful watching.

*Treatment.*—The patient should have his mouth cleansed, by gargling (if he can effect it) or otherwise, with solution of chlorate of potash or other detergent lotions; his strength should be sustained with liquid nourishment, which, if it cannot be swallowed, should be administered by the nose or rectum. Fomentations may be applied to the throat externally, and even leeches may be deemed advisable. It may also be necessary either to apply leeches to the tongue itself, or to make longitudinal incisions into it. If an abscess form, it should, of course, be opened. For general treatment, febrifuges may be given; and opium is of great value. It requires, however, to be given with much caution. If suffocation threaten, tracheotomy may need to be performed.

---

## VII. GRANULAR PHARYNGITIS

*Definition.*—A chronic inflammatory affection of the pharynx, characterised by the presence of miliary granulations.

*Causation.*—It is not always easy to determine the cause of this affection; but it appears to be frequently the result of repeated attacks of catarrhal inflammation induced by exposure to cold and wet, or by the local action of irritating substances, such as tobacco-smoke, especially in persons who are overworked or in impaired health. It often affects those who habitually over-exert themselves in speaking aloud or singing. It is mostly a disease of young adult life.

*Symptoms and progress.*—The granular condition, which is generally believed to be due mainly to enlargement of the pharyngeal glands, may affect any part of the pharynx or the whole of it, and may thus involve not only the region visible from the mouth, but also that related to the back of the nose, and may extend even to the mucous membrane of the upper part of the larynx. The affected surface usually presents enlarged and tortuous veins; and, though sometimes yielding a viscid mucus, is for the most part unnaturally dry. The symptoms vary a good deal. In some cases the patients suffer little, if at all. In other cases they complain of more or less constant catarrhal symptoms; such as dryness and discomfort, or actual pain in the throat, with tendency to swallow or to hawk

and cough in order to get rid of mucus or of the sense of irritation. The voice frequently becomes hoarse ; and swallowing, speaking, or singing may be attended with discomfort or pain. In aggravated cases considerable and irregular thickening, and even ulceration of the affected parts may take place ; and it is then not unusual for large quantities of thick greenish mucus to accumulate and concrete at the back of the pharynx, especially at night, and to be difficult of dislodgment.

*Treatment.*—Granular pharyngitis is not easily amenable to treatment. It is necessary in many cases for those who are liable to it to give up their habits (such as smoking) or their avocations (such as that of public speaking or singing), at any rate for a while. Change of air, attention to hygienic conditions, and tonic medicines are usually indicated. But local treatment is of chief importance ; the most efficacious being probably the direct application of glycerine of tannin, or of strong solution of nitrate of silver by means of a camel's-hair brush, or the use of the galvanic cautery.

---

## VIII. QUINSY (*Tonsillitis*)

### A. *Acute Tonsillitis*

*Causation.*—The surface of the tonsil becomes inflamed whenever spreading or general inflammation involves the mucous membrane of the mouth and fauces. Hence, in catarrh, aphthæ, and the like, the tonsils are necessarily implicated. Again, there are several affections in which inflammatory involvement of the substance of the tonsils forms an important and characteristic feature. We especially refer to scarlet fever and diphtheria. Deep-seated or parenchymatous inflammation of the tonsils, however, like ordinary catarrh, is a frequent consequence of exposure to cold or wet ; the two conditions, indeed, are not unapt to concur. Nevertheless it is a fact that many persons who are subject to catarrh, with all its usual associations, never suffer by any chance from tonsillitis ; and it is equally a fact that tonsillitis often occurs independently of the special symptoms of catarrh. The symptoms and course of tonsillitis, moreover, are very characteristic, and the affection, therefore, calls for independent consideration. Tonsillitis is mostly a disease of childhood, but when once it has developed it is apt to recur, and thus to be perpetuated into the period of adult life.

*Morbid anatomy.*—Simple or non-specific inflammation of the tonsils is characterised by inflammatory swelling of the tonsils themselves and of the soft tissues in their immediate neighbourhood, especially the pillars of the fauces, the soft palate and uvula, the base of the tongue, and the pharynx. The tonsil (for one is generally first and often solely affected) becomes increased in size, deeply congested, and infiltrated with inflammatory exudation and growth. The crypts upon its free surface produce superabundant epithelium, which accumulates in their orifices, forming

opaque, yellowish, creamy pellets. The lymphatic nodules of the interior undergo inflammatory overgrowth, and often soften, suppurate and run together, and ultimately form an abscess. The soft palate and pillars of the fauces become of a vivid red hue, swollen, tense and shining, and more or less displaced; and thus, if the swelling of the tonsil and surrounding parts be extreme, we find the soft palate on the affected side pushed downwards, forwards, and inwards, the anterior faucial pillar correspondingly displaced, and both together forming a smooth, tense, vividly red swelling with the convexity facing forwards. The swelling and displacement indeed of the surrounding parts are sometimes so great that the enlarged tonsil itself is almost concealed. When both tonsils are involved, their affection is sometimes concurrent, more frequently in sequence. Often indeed the one is getting well when its fellow first shows signs of disease. When the tonsils are both very large, they may meet one another in the mesial line, becoming flattened and sometimes ulcerated from mutual pressure, and between them almost completely closing the faucial canal. The uvula, which is usually swollen, tense, and congested, often clings to one of them; and it may be so much elongated as to hang into the upper part of the larynx. Further, the tongue gets covered with a thick creamy fur, and the glands at the angle of the jaw, and sometimes the salivary glands, share in the inflammation, and become hard and large.

*Symptoms and progress.*—The invasion of tonsillitis is almost always marked by the occurrence of severe febrile symptoms associated with soreness, itching or tingling, dryness and aching in the region of the fauces. The febrile symptoms increase in severity with the increase of the local affection, and with the cessation of the latter gradually, or, it may be, suddenly subside. At the beginning the patient experiences alternate flushes of heat and chills, and even distinct rigors; his temperature rises, and often reaches an elevation of at least  $102^{\circ}$ ; not unfrequently, indeed, by the time the disease has attained its maximum, it mounts to  $104^{\circ}$  or even  $105^{\circ}$ , and Dr. Haig-Brown records a case in which it reached  $107^{\circ}$ ; his pulse increases in frequency, rising to 100 or 120, and is at the same time more or less full and firm; his skin is hot and pungent, but with a marked tendency to remittent sweats; he complains of headache, pains in the back and limbs, thirst and anorexia; his bowels are confined, his urine dark-coloured and scanty, and occasionally albuminous. The appearances which the tonsils and interior of the mouth present may be gathered from the description which has been given of these parts. It remains to say that the patient has severe pains at the back of the throat and base of the tongue whenever he moves his jaws, or speaks, and especially whenever he opens his mouth widely or attempts to swallow. The pain then not unfrequently shoots along the Eustachian tubes to the ears. He has a constant desire to swallow in order to relieve his uneasiness, but the pain and difficulty of swallowing are so great that he permits the secretions to accumulate in his mouth; and, in attempting to swallow, fluids not unfrequently pass up into the nose. The quality of the voice is nasal and

characteristic. There is often deafness, and always more or less fulness and tenderness behind the angles of the jaw. The swollen tonsils indeed may be felt in these situations. If one tonsil only be inflamed, or both be simultaneously affected, the malady will probably attain its height in three or four days, and end in convalescence at the end of a week or ten days. Occasionally its course is yet more rapid, and the patient is well, or nearly so, in three or four days. But when one tonsil is affected after the other, the course of the disease is necessarily protracted. If an abscess form, as is usually the case when the attack is severe, the severity of the symptoms progressively increases up to the moment at which the abscess breaks. Then the tonsil suddenly shrinks within moderate dimensions, and the patient is probably at once restored to comparatively good health. The matter which escapes is fetid and thick, and usually swallowed. The symptoms of tonsillitis are severe out of all proportion to the seriousness and danger of the affection. Any other termination than that of recovery within a brief period is very rare. The interference with swallowing, which seems so serious, never prevents the taking of food for more than a very limited period. Occasionally, however, death results from suffocation, due either to the sudden bursting of a large abscess and the entrance of its contents into the larynx, or to the mechanical impediment which the inflamed and swollen parts interpose to respiration. Quinsy is occasionally associated with rheumatism, or intra-thoracic inflammation, and we have known an attack to be followed by nephritis and anasarca.

*Treatment.*—Tonsillitis is one of that large number of diseases which take their own course. It may, nevertheless, be relieved by appropriate measures. The patient should be submitted to the same plan of general treatment that has already been recommended as suitable for catarrh. Nor need there be much difference in respect of local treatment. Hot fomentations, or flannel, or cotton-wool may be applied to the exterior of the throat; and the patient be persuaded to gargle his fauces frequently with warm milk, or to allow the steam of boiling water to play upon them, or to suck black-currant jelly and such-like substances. Sucking lumps of ice, however, and the application of ice-cold compresses to the neck often give far greater relief than warmth. Astringent and stimulating gargles are often recommended, as is also the application of nitrate of silver. Such treatment, however, is more suitable to the period of convalescence, at which time also tonics and good food may be specially needed. Opium judiciously administered generally gives great relief. Salicylate of soda in large and frequent doses has been strongly recommended. When the swelling of the tonsil is extreme and the congestion intense, and the patient at the same time is suffering severely, relief may sometimes be afforded by scarifying or puncturing the tonsil. The value of such treatment, however, is chiefly seen when suppuration has taken place. Care should be exercised in puncturing the tonsil not to wound the large vessels which run along its outer aspect. The point of the lancet should be directed backwards, with an inclination inwards. But even if no large vessel be injured, dangerous hemorrhage occasionally ensues.

*B. Chronic Tonsillitis*

*Symptoms and progress.*—As a consequence, sometimes of frequently repeated attacks of acute tonsillitis, sometimes of chronic inflammation, the tonsils undergo gradual hypertrophy, and form indolent tumours, which more or less seriously diminish the size of the faucial passage, and occasionally come into actual contact with one another. The presence of such tumours may be scarcely apparent to the patient himself; but in many cases, especially if large, they give a peculiar quality to the voice, which is indescribable, but impossible not to recognise when once it has been pointed out; and not unfrequently there is associated with them chronic thickening of the mucous membrane of the pharynx and Eustachian tubes, together with deafness. Further, such patients are generally liable to frequent exacerbations of the affection.

*Treatment.*—Tonic medicines, iron and quinine and the like, good diet, fresh air, and healthful exercise are of great value in the treatment of chronic tonsillitis. It is commonly held that the application of strong solutions of nitrate of silver or of the solid caustic, or other such agents, is serviceable in promoting the disappearance of these bodies. Such applications are no doubt frequently beneficial in allaying inflammation affecting their surface. But the only effectual way of dealing with them is to remove them by the knife.

---

## IX. RETRO-PHARYNGEAL ABSCESS

*Causation.*—Retro-pharyngeal abscess is usually due to caries of the cervical vertebræ, and is sometimes one of its earliest indications; it may be connected also with suppuration in and about the tympanum and Eustachian tube, even when the bone is not involved. We have met with it in a case of aortic aneurysm.

*Symptoms and progress.*—A retro-pharyngeal abscess is situated, as its name indicates, between the posterior wall of the pharynx and the anterior aspect of the vertebræ, and forms a convex protrusion of greater or less extent and prominence at the back of the pharynx. It may be so high or so low as to escape detection by the usual method of observation; but in most cases it forms a visible bulging at the back of the throat. It is sometimes symmetrical, sometimes more or less one-sided, soft and yielding to the touch, and not necessarily presenting superficial congestion. It is liable to undergo perforation from time to time, to allow of the temporary escape of matter, and consequently to vary in bulk. Its presence is sometimes productive of pain and difficulty in swallowing, and has been known to impede respiration, and even to cause death by such impediment; but not unfrequently it is, for a time at least, simply a source of discomfort to the patient, in consequence of the pus which it exudes, the foul taste which it gives, and the fetor which it imparts to

the breath. The progress of the abscess depends mainly on that of the disease which produces it.

The *treatment*, apart from the use of tonics, which is generally clearly indicated, is essentially surgical.

---

## X. DRY MOUTH.

Dryness of mouth is a common incident in most febrile disorders; but a peculiar form of the affection has been described by Mr. J. Hutchinson and Dr. Hadden, and we have also seen examples of it in which, apparently independently of all other evidences of disease, the whole interior of the mouth becomes persistently and almost perfectly dry. This affection occurs mainly, if not exclusively, in persons advanced in life, and is probably of neurotic origin; at any rate it seems to have been induced in some instances by severe mental distress.

The dryness comes on sometimes gradually, sometimes almost suddenly, and seems to depend on suppression of the secretions alike of the salivary glands and of the mucous crypts. When fully developed the lips, the gums, the inner surface of the cheeks, the palate, and the tongue are all dry; the mucous membrane generally is smooth and glazed, and the tongue red, corrugated, or fissured. The surfaces are sometimes a little clammy, and the tongue consequently tends to cleave to the roof of the mouth; but, for the most part, neither during mastication nor at any other time is there any escape of saliva or exudation of moisture. The affection is attended with much discomfort, and more or less difficulty in mastication and in speech, but is free from pain, and is unassociated with any actual loss of taste or feeling, or any obvious disease of the salivary apparatus or of the chylopoietic viscera. It is said that the affection occasionally extends to the mucous membrane of the nose and to the lacrymal glands. There is reason to fear that it is, at any rate in aggravated cases, incurable.

Various remedies, such as jaborandi, mercury, iodide of potassium, and nervine tonics, have been tried without much benefit. Temporary relief, however, is given by the frequent sipping of fluids, and especially the application of glycerine.

---

## XI. OZÆNA

*Causation.*—This term is applied to all those cases which are attended with fetid discharge from the nose. The causes of ozæna are in some cases mere chronicity of inflammation of the mucous surface, in some ulcerative destruction or gangrene, and in a large proportion of cases caries or necrosis of the nasal bones. These several morbid conditions are for the most part connected, either with scrofula, with syphilis, with

lupus, or with polypoid or malignant growths occurring in the nasal cavities.

*Symptoms.*—The discharge which escapes from the nostrils varies considerably both in character and in quantity. Sometimes it differs little in appearance from ordinary mucus, often it is thick and purulent, sometimes it contains blood, sometimes it is thin and ichorous. It frequently also tends to concrete in the cavities of the nostrils into thick crusts. The accumulation of unhealthy discharges in the antrum and other sinuses connected with the nose often leads to their decomposition, and to fetor; and the escape of such discharges is apt to take place at irregular intervals. The nature of the stench which is emitted varies greatly both in quality and in intensity. In some cases it is horribly disgusting. Ozæna is generally attended with more or less complete loss of smell.

The source of fetor may, even in the absence of discharge, be readily ascertained by making the patient respire alternately through the mouth and nose, and ascertaining under which of these conditions it is chiefly developed.

*Treatment.*—For this purpose the determination of the cause is of fundamental importance. If it be syphilitic, antisymphilitic remedies must be given; if connected with enfeebled constitution, tonics and good diet must be enjoined. Under any circumstances the nose should be kept clean; it should be frequently washed out, by means of a syringe or the nasal douche, with a weak alkaline solution, or a weak solution of quinine, Condyl's fluid, chlorinated soda, chlorate of potash, or carbolic acid; and either stronger solutions of the same agents should be occasionally employed as injections, or appropriate powders should be frequently blown in or sniffed up. For the latter purpose Trousseau recommends bismuth diluted with an equal part of some inert powder, or white precipitate mixed with about forty times its weight of finely powdered sugar.

---

## XII. MORBID GROWTHS

A. *Tubercle.*—Miliary tubercles are described by Virchow as occasionally affecting the mucous surface of the tongue, palate, and nose, and there producing shallow sinuous ulcers, such as characterise the tubercular process in other mucous membranes. Tuberculosis of the tongue for the most part affects the posterior part of the organ, and is generally associated with similar disease about the fauces. Tubercular ulcers affecting these situations are much like the tubercular ulcers of other mucous membranes. They are at first shallow, circular, ashy pits, which run together, and form intractable, slowly spreading ulcers, various in size, sinuous in outline, with irregular thickened congested margins, and depressed shreddy greyish surface.

B. *Syphilis.*—Syphilis in its secondary and tertiary stages is very apt to affect the tract of mucous membrane now under consideration.

1. Erythematous patches, for the most part symmetrical, may appear on

the pharynx or palate, inside the lips, or elsewhere in the mouth, during the prevalence of the secondary cutaneous eruption. 2. Mucous tubercles may develop during the same period, principally on the lips, dorsum and edges of the tongue, tonsils and palate, and in the pharynx; and shallow ulcers, secondary to these tubercles, or of independent origin, are not unfrequent in the same situations. 3. At a later period of the disease deep ulcers appear, most commonly in the soft palate, tonsils, fauces, and pharynx, frequently spreading in a serpiginous manner, and gradually involving a wide extent of surface or penetrating deeply, and in either case leading to serious destruction of tissue. Lastly, gummatous tumours are not uncommonly developed in the soft palate and pharynx, but more especially in the substance of the tongue.

For a further account of these affections, and their treatment, we must refer to the article upon syphilis.

C. *Malignant tumours*.—Tumours of various kinds originate in, or involve, the mucous membrane of the mouth and fauces, or the organs which are contained within the mouth. But it scarcely falls within the province of the physician either to investigate or to treat them. Malignant affections of these parts alone have any medical interest. They are not uncommon.

In persons advanced in years, epithelioma of the lips (more especially of the lower lip) is apt to occur; in those who have attained or passed middle life a similar affection of the tongue is not uncommon; and not unfrequently, under the same circumstance of age, malignant disease (mostly epithelioma but sometimes carcinoma, sometimes sarcoma) becomes developed in some part of the fauces or pharynx. Again, malignant tumours (commonly some soft variety of carcinoma or sarcoma) occasionally form in connection with the mucous membrane of the nose, for the most part in young children or persons advanced in life. Further, sarcomatous and carcinomatous tumours, originating either in periosteum or in bone, form outgrowths from the bones of the upper and lower jaws, from those bounding the nasal cavity, and from the cervical vertebræ.

Malignant tumours of the mucous membrane are nearly always primary; they are often slow and insidious in their progress, and apt at first to be mistaken for some trivial affection; they are especially liable when they have made some progress to be confounded with syphilitic affections. That they are not syphilitic is, however, soon revealed by the total inoperativeness upon them of antisyphilitic treatment, and by their further progress. They gradually and surely invade the surrounding textures, gradually ulcerate and slough (causing more and more extensive destruction, and yielding a foul discharge), and always before long involve the neighbouring lymphatic glands. These then form gradually enlarging tumours, which presently undergo precisely the same changes as the primary tumour. The diagnosis of these cases, which is often very uncertain in the beginning, rests mainly upon microscopic examination, and on careful observation of their gradual and characteristic progress.

Their *treatment* is purely surgical.

## SECTION II.—DISEASES OF THE ŒSOPHAGUS

## I. INTRODUCTORY REMARKS

*Anatomical relations.*—The œsophagus commences at the cricoid cartilage, opposite the lower border of the fifth cervical vertebra, and runs down along the spine, a little to the left side, as far as the ninth dorsal vertebra, opposite which it penetrates the diaphragm, and opens into the stomach. In the neck it has the trachea in front of it, with the recurrent laryngeal nerves between them, and on either side the common carotid artery. In the chest it is covered in front by the lower part of the trachea and then crossed by the left bronchus, after which it comes into contact with the pericardium. On either side of it is the pleura. The transverse and descending arch of the aorta cross the front and left side of the œsophagus on the level of the second and third dorsal vertebræ; and the thoracic portion of that vessel lies to its left and behind it throughout the rest of its course, excepting just as it perforates the diaphragm, when the aorta slips altogether behind it.

## II. INFLAMMATION OF THE ŒSOPHAGUS

*Causation and morbid anatomy.*—The œsophagus is liable to share in all those inflammatory conditions which affect the pharynx and larynx. We have pointed out that the inflammation of a simple ‘cold’ may travel downwards along this tube; and when inflammation of special intensity involves the organs in relation with it, the œsophageal inflammation may be equally intense. Occasionally, indeed, under such circumstances thickening of its walls, with purulent infiltration of them and of the surrounding connective tissue, may extend from the pharynx to the cardiac orifice of the stomach. Further, the specific eruptions of some of the infectious fevers may involve the œsophagus, the diphtheritic false membrane may pervade its whole extent, and aphthous patches may form here and there upon it. Inflammation is sometimes also the result of swallowing boiling water or corrosive substances, such as the mineral acids, caustic alkalies, and other chemical agents.

*Symptoms.*—In nearly all the above cases the œsophageal inflammation is associated with similar but probably more severe inflammation, either of the larynx, pharynx, and fauces above, or of the stomach below; and the graver symptoms of these other affections tend to mask the presence of the œsophageal complication. The special indications of inflammation of the œsophagus are: heat and pain in the course of that tube; aggravation of pain in the same situation during the act of swallowing, and in severe cases inability to swallow; and tenderness on pressure applied to the neck in the situation of the œsophagus. The absence, however, of such symptoms does not disprove the presence of either general slight inflammation, or limited tracts of inflammation.

III. CHRONIC AND OBSTRUCTIVE DISEASES OF THE  
ŒSOPHAGUSA. *Ulceration*

*Causation and morbid anatomy.*—The most frequent causes of ulceration are mechanical violence, and the operation of destructive reagents, to which may be added perforation of the œsophagus from without.

Small ulcers and mere excoriations doubtless get well, as a rule, without leaving any permanent ill-effects behind; but when ulcers are extensive and deep, even though they be free from any malignant taint, they are liable sooner or later to induce serious results. Of these the most important is cicatrisation, with consequent contraction of the calibre of the tube, and the supervention of a stricture which tends to become more and more tight. Other results are the formation of a sinus between the œsophagus and trachea, or left bronchus, and the perforation of an artery.

B. *Morbid Growths*

*Morbid anatomy.*—The œsophagus is occasionally the seat of syphilitic disease with ulceration, which by cicatrisation may cause more or less serious contraction and obstruction. Of all adventitious formations, however, the most common and the gravest are of a malignant character. These are chiefly met with after the age of 40 or 45, and in the great majority of cases are of primary origin. The most frequent variety of malignant disease probably is epithelioma; but encephaloid and scirrhus cancers are not unfrequent; and colloid cancer also has been observed. The seat of the disease varies. In some cases it occupies the upper extremity of the tube, probably then involving also the contiguous pharynx and larynx; in some cases it is found at the lower extremity, when it is often associated with similar disease of the neighbouring cardiac extremity of the stomach; but in the greater number of cases it occurs in some intermediate region, and very frequently in that part of the tube which is in relation with the trachea and bronchi. The affection, when primary, usually commences at some spot in the thickness of the mucous and sub-mucous tissues, whence it spreads, superficially, so that before long it probably occupies three or four inches of the length of the œsophagus and its whole circumference; and in depth, so that sooner or later it implicates the whole thickness of the walls, and probably invades also the trachea or other neighbouring tissues and organs. The free aspect of the growth is at first somewhat nodulated; but the nodules running together soon form flattish elevations, in connection with which, before long, ulceration, sloughing, and the formation of fungous outgrowths take place. The thickened walls and nodulated outgrowths reduce the calibre of the œsophagus, and sometimes render it almost impervious. The subsequent ulcerative destruction occasionally leads to its imperfect restoration. When the disease is of the colloid variety, the close-set vesicles of the growth open on the mucous surface, and abundant, clear, glairy fluid escapes.

In the progress of malignant disease various accidents are apt to arise. Sometimes the trachea or left bronchus gets perforated, and a communication between it and the œsophagus established; sometimes the œsophagus opens into the posterior mediastinum, or externally, or communicates by ulceration with one of the œsophageal or intercostal arteries, or the left subclavian. And, besides the mere spread by contiguity, œsophageal malignant growths, like those of other parts, soon cause secondary disease in the neighbouring lymphatic glands, and, if the patient survive sufficiently long, disease of remote organs. The involvement of lymphatic glands, especially if they be those of the neck, is very often valuable as an aid to diagnosis. Further, it not very unfrequently happens that the recurrent laryngeal nerve, especially that of the left side, is implicated, and paralysis of the corresponding vocal cord induced.

### C. *Affections implicating the Œsophagus from without*

*Causation and morbid anatomy.*—The œsophagus is apt to be pressed upon or otherwise affected by tumours and other morbid conditions originating externally to it; and the patient's sufferings in many such cases are mainly, if not entirely, due to interference with the functions of this canal. Thus it may be compressed by an overgrown thyroid body encircling the trachea and acting upon it laterally; by a carotid or innominate aneurysm, or an aneurysm of the descending arch or thoracic aorta; by enlargements of the bronchial glands or other mediastinal growths; by tumours springing from the vertebræ; by abscesses; or even by a distended pericardium or dilated auricles.

Again, aneurysms and abscesses not unfrequently open into the œsophagus with a sudden and copious escape of blood or pus. Occasionally they open simultaneously into the œsophagus and trachea, or one of the bronchi, causing more or less free communication between these tubes. And further, rupture of an aneurysm of the lower part of the thoracic aorta occasionally causes an accumulation of coagulum around the cardiac end of the œsophagus with complete obstruction of its passage.

### D. *Dilatation*

*Causation and morbid anatomy.*—Whenever a stricture of the œsophagus has existed for any length of time, a tendency shows itself for the part of the tube below to contract and even to undergo atrophy, and for the part of the tube above to become dilated, and at the same time hypertrophied in respect of its muscular parietes. The same results indeed follow here that follow in the case of the bladder when there is stricture of the urethra. The dilatation and hypertrophy are in the majority of cases not strikingly apparent; sometimes, however, they are considerable, and especially when stricture is situated low down, is non-malignant, and has been in existence for many years. Under such circumstances the œsophagus becomes dilated either in its whole length, or in a part of its length only, forming an elongated pouch, which may have a circumference of five or six inches. Such dilatations are sometimes discovered in cases where

their development cannot be traced to the existence of any mechanical impediment. It seems obvious, however, that they must even here be due, partly to distension by accumulated contents, and partly to powerful and sustained efforts of the muscular tunic to drive these contents onwards ; and that hence there must have been in the first instance some weakness or sluggishness of the tube, some virtual impediment, permitting of such accumulation.

#### *E. Spasm and Paralysis*

Spasmodic stricture of the œsophagus generally occurs in nervous persons, and especially in hysterical women. It may appear, however, without obvious cause in persons of quite different nervous organisation ; and not unfrequently supervenes in the course of organic œsophageal disease, causing temporary aggravation of the patient's symptoms.

Paralytic conditions of the œsophagus are rare. They may be hysterical, or dependent on profound affection of the central nervous organs. Occasionally they are a result of inflammation of the tube.

#### *F. Symptoms. Dysphagia*

A common symptom of nearly all the above lesions is dysphagia, or difficulty or pain in swallowing. It is this symptom, indeed, which generally first attracts attention to the œsophagus as the seat of disease ; and it is only by the subsequent history of the case, by the supervision or non-supervention of other phenomena (oftentimes mere hints), that we are enabled to ascertain the exact nature of the disease which is present.

Dysphagia is a symptom of many other morbid conditions besides these ; and especially of affections of the mouth, fauces, larynx, and pharynx. But under these circumstances, it is for the most part merely a subordinate symptom of diseases otherwise well characterised. It is very different, however, when the impediment to swallowing exists in the course of the œsophagus ; it is then not merely a symptom, but it is *the* symptom by which alone, in many cases, the presence of disease is indicated.

The symptoms of organic obstruction are usually of slow development ; the patient perhaps first experiences an occasional hitch in the passage of food to the stomach—a hitch which is chiefly obvious when solids are being swallowed. This is variable, partly because the bulk and character of the swallowed bolus differ from time to time, and partly from the occasional superaddition of spasmodic contraction. Further, it is probably always referred to a definite point, and is not unfrequently associated with soreness or pain there. For some time probably these symptoms have little attention paid to them ; but gradually they increase in severity and constancy, and attend the swallowing of both liquids and solids ; further, the food before long begins to accumulate above the seat of obstruction, and hence to be regurgitated after a longer or shorter period of time with a kind of gulp—an effort which often has little or no resemblance to ordinary vomiting. The period at which regurgitation

takes place after deglutition depends partly on the seat of obstruction, partly on the degree of irritability of the œsophagus, and partly upon its condition as to dilatation. Generally, when the obstruction is high up, the regurgitation is immediate; when, however, it is low down, as at the cardiac extremity, the return of food is usually delayed for a few seconds or minutes, and in some cases for half an hour, an hour, or more. The food indeed may be retained so long as to undergo early putrefactive changes, but the vomit contains neither the acid secretions of the stomach nor bile. As the disease progresses, the patient has to restrict his diet to slops, and ere long finds that he can take even such food as this only in the smallest quantities, and with difficulty and distress. He then rapidly emaciates, his abdomen becomes hollow, and, if no fatal complication ensue, he dies after a longer or shorter period of suffering from simple starvation. Such deaths are usually exceedingly distressing, because the patient, as a rule, retains his mental powers unimpaired to the last, and craves for nourishment which cannot be administered to him. These are the general symptoms of œsophageal obstruction ending fatally. But the progress of the case is usually largely modified by the nature of the disease on which it depends.

If the case be one of simple stricture from a cicatrix, its course is generally much protracted. And, although such cases are often ultimately fatal, instances are on record in which patients have lived, though with more or less discomfort, to a good old age, and have then died of some other ailment. It is in them especially that dilatation of the tube above the stricture with compensatory hypertrophy takes place—conditions which, confined within certain limits, tend to neutralise the effects of the stricture.

If the case be one of malignant disease, this fact is often for a while incapable of determination. The points which especially indicate it are: the comparative rapidity with which the case goes on from bad to worse; the advanced age of the patient; the appearance of indurated glands in the neck; the supervention of hoarseness or impurity of voice from implication of the recurrent laryngeal nerve; and the discharge from the œsophagus, in company with regurgitated food, of offensive, puriform, or sanious matter or detritus. Further, the sudden discharge of blood in large quantity, or the establishment of a communication between the œsophagus and air-passages, strongly indicates, though it does not prove absolutely, the presence of a malignant ulcer. Copious hemorrhage is occasionally one of the earliest phenomena.

The symptoms due to the pressure of external growths differ but little from those arising from actual disease of the œsophageal walls; indeed, the latter usually after a time becomes distinctly implicated. To aid our diagnosis we must carefully explore the neck and thorax, in order to ascertain whether there be an enlarged thyroid body, a mediastinal growth, an aneurysm, or any other form of tumour. But, although in many such cases we may be enabled to form a correct diagnosis, in many all our efforts will necessarily be fruitless.

We have stated that organic obstruction is usually of slow development; nevertheless it occasionally arises with sudden completeness. In the case, for example, of obstruction from the compression exerted by a circle of effused blood around the cardiac orifice, the symptoms occur quite suddenly, and the patient dies probably of starvation at the end of ten days or a fortnight.

An important point in reference to œsophageal obstruction is to ascertain its exact seat. It is important, partly in connection with the treatment to be adopted, partly as an element in determining the exact nature of the obstruction. Its site may be pretty correctly determined in many cases by the sensations of the patient. It is often indicated to some extent by the phenomena already considered which follow the ingestion of a few mouthfuls of milk or other food. It is, however, on the passage of the bougie, and the determination of the exact point at which its progress gets arrested, that our main reliance must be placed. Another occasionally useful method is that of auscultating the œsophagus. If the stethoscope be applied to the back in the course of this tube, and the person examined be made to swallow a mouthful of fluid, its momentary passage in the form of a compact mass is distinctly audible. If, however, an impediment exist, especially if the impediment be considerable, there will be some obvious delay in the passage of the mass at its seat; and moreover, the mass, instead of passing in a compact form, will probably trickle through in dribblets, and its passage be attended with comparatively prolonged gurgling. It is not sufficient, however, to determine on one occasion the existence of gurgling at a particular spot. We must ascertain, by repeated observation, whether that localised gurgling is permanent or not.

Dilatation alone of the œsophagus is an impediment to the act of deglutition. The presence of dilatation, even if there be muscular hypertrophy, necessarily renders the œsophagus a less efficient instrument for the propulsion of its contents. These instead of being driven readily and rapidly onwards, accumulate in the flaccid bag, and thence find their way fitfully into the stomach. One of the most interesting phenomena connected with dilatation is the tendency which there often is for the accumulated contents of the tube to be regurgitated by an effort, more or less voluntary, into the mouth, as in the act of rumination.

Spasmodic stricture is apt to come and go more or less suddenly, and, if it be long continued, to present intermissions or variations of severity. It is attended with many of the symptoms of organic stricture, for which it may easily be mistaken, and may even, if neglected, lead to death by starvation. The diagnosis rests partly on the patient's history and general state of health, partly on the variableness of the œsophageal obstruction, and partly on the evidence furnished by the unopposed passage of the bougie. It may affect any part of the œsophagus. In one case under our care a man of 50 had spasmodic stricture of the upper part of the tube, which for a week prevented him from swallowing the least portion of fluid or solid food. The act of deglutition was performed,

but followed immediately by the spasmodic ejection of whatever he had attempted to swallow. He was permanently cured by a single introduction of the bougie. In another case an hysterical girl had obstruction of the lower part of the œsophagus. For many weeks little, if any, food entered the stomach; but it was retained in the œsophagus for a variable time, and then regurgitated without the ordinary phenomena of vomiting. In this case also a cure was effected by the use of the bougie.

The symptoms due to paralysis of the gullet are also mainly those of obstruction. The food fails to be transmitted onwards to the stomach, and at the same time tends to accumulate in the tube, to distend it, and sooner or later to be regurgitated. The bougie passes without impediment.

### G. *Treatment*

Œsophageal obstruction is, in a very large proportion of cases, difficult and unsatisfactory of treatment. If it be functional only, the passage of a bougie will sometimes at once restore the capability of swallowing. The permanent cure, however, of such cases is often to be obtained only by curing the nervous conditions on which the obstruction depends. If, on the other hand, the obstruction be organic, the tendency of the disease is to render the occlusion of the tube more and more complete, and actual cure is probably out of the question. We have no drugs which promote the absorption of cicatricial bands, or of carcinomatous or other tumours. We can, however, in some cases, by surgical means, check the progress of contraction, and even cause dilatation of a part already strictured. We have pointed out the importance, for diagnostic purposes, of passing an œsophageal bougie. The careful passage of a bougie through a stricture, and the repetition of the operation at intervals with instruments of gradually increasing size, will not only aid us in diagnosis, but in some cases relieve the stricture materially, and maintain that relief. The passing of a bougie, however, through an obstructed œsophagus is an operation of much delicacy, and attended with no inconsiderable danger, especially if the impediment consist of a tract of soft ulcerating cancerous material, or be due to the pressure of a thoracic aneurysm. The bougie may in fact, under such circumstances, readily form a false passage into either the trachea, the mediastinum, or the cavity of an aneurysm, and so induce speedily fatal symptoms. So great is this danger, that many practitioners regard this mode of treatment as almost entirely inadmissible; and indeed it must, we think, be conceded that it is quite inadmissible in cases of compression of the œsophagus by an aneurysm, and in cases of malignant disease in which ulceration or sloughing has taken place. But there cannot, we think, be a doubt of the benefit which may accrue from the regulated use of the bougie, in skilful hands, in cases of simple stricture. The dilator suggested by Dr. M. Mackenzie is well suited for such cases. The passage of the bougie has occasionally ruptured an abscess to which obstruction was due, and in this way cured the patient. When the ingestion of food is largely interfered with, and the patient shows manifest signs of starvation, the question as to whether he

may be supplied with food by any other route than the œsophagus arises. The use of nutritive enemata is one of the methods which suggest themselves, and is often useful in prolonging life. Another method is that of laying open the stomach itself through the anterior abdominal wall, and feeding the patient through the artificial opening. This operation has occasionally been performed, and although the cases have not been very successful, the feasibility of the operation has been clearly demonstrated. When the stricture is simply spasmodic, it may, as we have already shown, generally be treated successfully by the employment of the bougie. In those cases in which the dysphagia is due to paralysis or simple dilatation of the œsophagus, the patient may, of course, be fed and life maintained by the constant use of the stomach-pump.

---

### SECTION III.—DISEASES OF THE STOMACH, INTESTINES, AND PERITONEUM

#### I. INTRODUCTORY REMARKS

##### A. *Anatomical Relations*

The surface of the abdomen is artificially divided into regions which are convenient in determining the relations of the organs situated within. This division is usually effected by drawing two horizontal lines: one above, from the lowest point to which the ribs descend on the one side to the corresponding point on the other side; one below, between the anterior superior spines of the iliac bones; and then intersecting them by two vertical lines drawn, one on either side, from the cartilage of the eighth rib above to the centre of Poupart's ligament below. Nine unequal spaces are thus mapped out; of which the three occupying the median aspect of the abdomen are, from above downwards, the *epigastrium* or *scrobiculus cordis*, the *umbilical region*, and the *hypogastrium*; and the three on either side are, in the same order, the *hypochondrium*, the *lumbar region*, and the *iliac region*. The hypochondriac and iliac regions are small and triangular; the lumbar extend round to the spine, occupying on either side the whole interval between the ribs and the crest of the ilium, and are, therefore, of considerable extent.

The *epigastric* region is occupied mainly by the stomach, inclusive of its pyloric extremity, portions of the right and left lobes of the liver appearing above on either side of the ensiform cartilage; more deeply seated lie the hepatic vessels, pancreas, cœliac axis, and semilunar ganglia. The *umbilical* and *hypogastric* regions are occupied almost exclusively by the convolutions of the small intestine; along the upper part passes the transverse colon, and into the lower part ascend the distended bladder and the gravid uterus. Deep in these regions lie the third portion of the duodenum above, and the mesentery with its vessels and glands below. The aorta divides opposite the navel. The *right hypochondriac* region contains the lower edge of the right lobe of the liver with the gall-

bladder, and the hepatic flexure of the colon; more deeply the first and second portions of the duodenum; and more deeply still the upper part of the right kidney and the supra-renal capsule. The *left hypochondrium* is occupied by the lower portion of the spleen, the cardiac extremity of the stomach, the splenic flexure of the colon, and more deeply by the upper part of the left kidney and the supra-renal body. Each *lumbar region* is occupied by the convolutions of the small intestine, laterally by the ascending or descending colon, and farther back by the lower half of one of the kidneys. In the *right iliac region* is placed the cæcum, in the *left* the sigmoid flexure.

### B. Examination of the Abdomen

The direct examination of the abdomen in all cases of disease of the contained viscera, and in all affections attended with symptoms referrible to these organs, should never be neglected. And in conducting such examinations, and forming our opinions from them, we must always recollect, not only the normal positions of the parts within, but the facts that even in health many organs are liable to considerable changes of bulk and position, and that in disease such changes are often in the highest degree misleading. Apart from rectal, vaginal, and urethral examinations, which we shall not now enter upon, the methods of investigation include inspection, palpation, percussion, and auscultation.

1. *Inspection*.—Much may often be learnt by simple inspection. The *form* of the abdomen in many diseases is no doubt entirely normal; but it is often importantly and characteristically modified. In cases of extreme emaciation, especially from starvation, the surface becomes flattened or even concave; and a somewhat similar retraction of the parietes is frequently observed in cerebral disease, particularly among children. On the other hand, the abdomen is often more prominent than natural. This condition may be due to fat in the parietes, or to anasarca; in which case the general symmetry of the belly is maintained, but the umbilicus is usually deeply sunk. It may depend on distension of the stomach and bowels; when not unfrequently the abdominal walls (especially if they be thin) are moulded in some degree to the alternate depressions and elevations of the subjacent organs. When distension is the consequence of ascitic accumulation, the belly (owing to the influence of gravitation) has a tendency, as the patient lies on his back, to expand laterally and to bulge in the flanks—a tendency, however, which often disappears when the accumulation becomes very large, and may be masked by coincident tympanites or rigidity of the parietes. Enlargement due to hypertrophy of solid organs, to tumours, or to abscesses, is rarely symmetrical. The *movements* of the abdominal walls are often significant. In pericarditis and pleurisy, and especially in paralytic affections of the diaphragm, and peritonitis, with other inflammatory affections of the abdominal organs, the diaphragm is inactive, and the surface of the belly remains quiescent during respiration. In cases of distension of the stomach or bowels, especially if it be due to any mechanical impediment to their action, the peristaltic move-

ments of the dilated organs may often be distinctly seen and traced. It need scarcely be added that the movements of the fœtus in the gravid uterus are distinctly visible. The *condition of the parietes*, again, may be of service to us. We may note the presence or absence of eruptions, or of dilated veins which generally accompany ascites, tumours, and obstructive disease of the portal vein, vena cava, or iliac veins. We may also observe whether they present circumscribed redness, brawniness, or swelling such as indicates the pointing of an abscess or the extension of inflammation from beneath, or whether there be any cutaneous or subcutaneous tumour, or an umbilical or any other hernia. Further, it may be remarked, not only that abdominal walls which have been the seat of much dropsical effusion or fatty accumulation fall into wrinkles when the fluid or fat disappears, but also that when once the abdomen has been largely distended (whether by pregnancy, ascites, or any other condition) they are liable to present those atrophic lines which habitually follow childbirth.

2. *Palpation*.—By manual or tactile examination we distinguish the different degrees of hardness, softness, resistance, and elasticity of the abdominal walls and subjacent parts, and can thus often determine the size, shape, quality, and relations of tumours. Moreover, we may recognise the fluctuation due to the presence of fluid, the pulsation of arteries and aneurysms, the thrill or crepitation resulting from inflammatory deposit, and the peristaltic movements of the stomach and bowels.

When the parietes are flaccid, especially if they be at the same time thin, we may sometimes by careful manipulation map out the form of the kidneys and other deep-seated solid organs. Indeed, under such circumstances the kidneys have been mistaken for tumours, and the abdominal arteries (especially those which lie on the promontory of the sacrum) for an aneurysm. When the walls are rigid (as in fact they are only too apt to be in those cases where examination is most needed) it is often exceedingly difficult to determine the condition of parts within. Moreover, portions of the rigid recti muscles are then very liable to be mistaken for tumours. In this case the patient should be made to lie on his back with elevated shoulders and knees, and heels pressed into the bed; and then the physician with warm hand or hands should press quietly but firmly on the abdomen, making the patient from time to time draw a deep breath. By such means, and taking constant advantage of each momentary relaxation, he may often in a short time overcome the muscular rigidity, and learn all that is necessary with regard to the subjacent organs. If these measures fail, the patient must be examined under the influence of anæsthetics.

The source of a tumour is in great measure distinguishable by its site and relations to the abdominal organs. We need not particularise the different localities in which we should expect to discover tumours of the liver, spleen, kidneys, or other viscera. We may, however, point out the importance and mode of determining whether a tumour be in the abdominal walls or adherent to them, or spring from the back of the cavity, or be connected with some of the movable parts within. A tumour

of the walls necessarily rises and sinks with the walls during respiration. A tumour connected with the liver, spleen, stomach, bowels, or omentum ascends and descends with the movements of the diaphragm, and, if unattached to the abdominal walls in front, can be distinctly felt to glide under them. This locomotion, dependent on the diaphragm, is of course most obvious in the case of tumours resting against the diaphragm or near it. Tumours springing from the kidneys or back of the abdomen are usually fixed, or, if movable at all, generally slightly in the transverse direction. Many growths connected with the stomach, bowels, ovaries, and peritoneum are freely movable, either under the hand of the examiner or with change of position. The form, size, and consistence of tumours, and the presence or absence of fluctuation in them, are points of importance.

The presence of fluid in the peritoneal cavity is generally attended with the sense of fluctuation. This is best obtained by pressing the left hand firmly and flat upon the abdomen, and then giving a sharp tap or fillip with the fingers of the opposite hand. It is most marked when the fluid is abundant, and the walls thin and tense. The sense of fluctuation comprises two elements: the one an instantaneous impulse conveyed through the fluid and not generally very perceptible; the other a wave which travels over its surface and involves the abdominal parietes. The latter is what is usually meant by the term; but it must be remarked that it (or something very like it) is occasionally observed in flaccid abdomens free from dropsy, and that it may be arrested or annulled by pressure made on the abdomen between the finger which percusses and the hand which receives the impression. In connection with the presence of ascites it may be observed that a layer of fluid, varying, say, from half to one inch in thickness, often intervenes between the upper surface of an enlarged liver and the anterior abdominal walls; and that the presence of the liver may then often be readily detected by pressing the finger perpendicularly with suddenness and force, and thus displacing the fluid and coming into sudden contact with the surface of the solid organ.

3. *Percussion*.—On percussing the abdomen we obtain, as a general rule, resonance or dullness, according as we operate over the stomach and bowels on the one hand, or over the solid organs or accumulations of solid matter or fluid on the other. Abdominal resonance is higher pitched and more musical than that elicited over the lungs. It is also much more variable in health, owing to the varying distension of the different parts of the alimentary canal. The percussion note is of course higher according as the tube percussed is narrower; thus deeper notes are usually obtained over the stomach than over the colon, and over the colon than over the small intestine; and hence occasionally by percussion alone the situation and limits of a distended stomach or colon may be readily determined. But in morbid states (which need not here be specified) the stomach may contract so as to yield a note like that of the healthy ileum, or the ileum or colon may become so much dilated as to furnish a note like that usually belonging to the stomach. Although percussion for

the most part gives a dull sound over solid organs, it is an important fact that distinct resonance may often be elicited over the thin edge of the liver, due to the liver and abdominal parietes vibrating together over the subjacent stomach. Occasionally also such resonance may be elicited over the spleen. The determination of the exact distribution of resonance and dullness is often very important in reference to the recognition of the presence of fluid and the diagnosis of abdominal tumours. In ascites the fluid, and consequently the relative positions of resonance and dullness, generally shift readily with the movements of the patient's body; and similar though more limited changes often occur in connection with the gravitation of the fluid or semi-fluid contents of the stomach and bowels. Further, the course which the ascending, descending, or transverse colon may take in relation to a tumour, often decides for us whether this arises in the kidney, liver, retro-peritoneal glands, or some other part. It is necessary, therefore, to bear in mind that a line of bowel lying superficially to a solid mass may be readily overlooked if care be not taken in the examination; for if, as in ordinary percussion, the finger of the left hand be pressed upon the part to be percussed, the bowel may be readily flattened under its influence, and dullness result. In all such cases, and indeed generally in abdominal percussion, when we are anxious to make a minute and critical examination of the condition of parts lying immediately under the walls, it is best to percuss by simply filliping the surface with the nail of the right forefinger. Of the peculiar prolonged thrill often observed on percussion over an hydatid tumour we shall speak hereafter.

4. *Auscultation*.—Of course gurgling and musical sounds of all sorts may be heard with the stethoscope over the stomach and alimentary canal, but little or nothing is to be learnt from them. Besides these, arterial murmurs due to the presence of aneurysms, or to the pressure of tumours or of the stethoscope, venous murmurs in connection with the gravid uterus, abdominal tumours, or dilated veins, the beats of the fœtal heart and friction sounds in connection with hepatic or splenic peritonitis, may be met with under different circumstances.

---

## II. GASTRITIS

*Causation*.—Acute gastritis in its severest form is exceedingly rare, unless it be the result of the direct application of irritant or corrosive substances to the mucous surface of the stomach. Its milder varieties, on the other hand, are very common at all ages and in both sexes, and from their mildness not unfrequently escape notice. The causes of gastritis are various; and include the ingestion of irritant or corrosive substances, the use of food which is ill-masticated, too abundant, or unwholesome (therefore, excess in eating and the abuse of alcohol), exposure to cold, and other atmospheric influences. Among predisposing causes must be enumerated constitutional debility, tuberculosis, various acute febrile complaints, heart, lung, and renal disease, and cirrhosis of the liver.

*Morbid anatomy.*—Slight inflammation, though obvious enough when seen, as in the case of Alexis St. Martin, during life, often leaves little trace of its existence after death. It is indicated by patchy congestion; enlargement of the epithelial cells, with a cloudy condition of their protoplasm, and the appearance of fat-granules within them; similar changes in the cells of the mucous glands; and hypertrophy of the lymphatic tissue. These conditions involve some degree of thickening and softening of the mucous membrane, and are attended with the formation of a greater or less abundance of ropy alkaline mucus, and diminished secretion of the true gastric juice. But these are not the only changes. Frequently, small extravasations of blood take place here and there into the substance of the mucous membrane, and small quantities of blood may even escape into the cavity of the stomach; and sometimes erosions, shallow ulcers, or superficial sloughs are developed. Some of the latter appear to be connected with previous hemorrhagic infiltration, if not dependent on it. When inflammation is due to the action of corrosive substances, the morbid appearances are determined largely by their several peculiarities of chemical action. There is usually, however, intense congestion, with more or less extensive destruction of the mucous membrane. Inflammation involving the whole thickness of the gastric walls is rare as an idiopathic affection. In these cases they are swollen in their entire thickness, sometimes infiltrated with simple inflammatory exudation, or pus, sometimes presenting scattered abscesses.

The morbid anatomy of chronic inflammation differs little from that of the acute affection. There is generally, however, less congestion and more degeneration. The mucous membrane is usually thicker than normal, pale, and comparatively tough. It may present extravasations of blood, and excoriations or ulcers. But more frequently it is studded here and there with black or slate-coloured spots, which are the pigmental remains of old extravasations or congestions; and with opaque white patches, which are due to fatty degeneration of the epithelial contents of groups of gland-tubes, and even of the corpuscles of the connective tissue between them, and are often associated with atrophy and shrivelling of the glands, and a tendency to the formation of cysts.

*Symptoms and progress.*—1. In severe idiopathic gastritis, as also in gastritis due to irritant poisoning, the symptoms are of an exceedingly violent character. The patient suffers from intense burning and shooting pain in the epigastrium and lower part of the chest in front, and between the shoulders, attended with rigidity and retraction of the abdominal muscles; extreme tenderness on pressure in the epigastric region; aggravation of pain on drawing a deep breath, with consequent shallow respiration; nausea, retching, and vomiting, not only after everything that is taken into the stomach, but even when the organ is empty; total loss of appetite; intense thirst; and collapse, marked by extreme feebleness of pulse, coldness and pallor of surface, cold perspirations, and tendency to faint. Besides these symptoms, distressing hiccough usually supervenes, and the bowels may become loose. The character of the vomit depends on circum-

stances. Generally, however, it comprises mucus (which is often mingled with altered blood), bile, and of course such matters as have been swallowed. The supervention of collapse, which forms so marked a phenomenon of the affection, is preceded by heat of skin and other febrile symptoms, which, however, soon subside. When the case ends fatally, death is mostly due to prostration; and the patient usually retains consciousness to the last. The date at which death supervenes varies generally between one and six or seven days. If recovery take place, it is usually protracted.

2. In the commoner and milder forms of acute gastritis, the symptoms are essentially the same as those which characterise the graver attacks: namely, heat or aching in the region of the stomach; tenderness on pressure in the epigastrium, with more or less rigidity of the abdominal muscles, especially the recti, and the endeavour to obtain ease by bending the body forwards and restraining the action of the diaphragm; irritability of stomach, with tendency to eructation and to reject by vomiting whatever is taken into it; anorexia, thirst, and febrile disturbance. Besides which, the tongue is usually coated, and there is headache, with intolerance of light, depression of spirits, and disturbed sleep. The symptoms are subject, however, to great variety, and even the most characteristic of them may be absent.

Pain in the stomach may fail wholly, or exist as a mere sensation of warmth, or it may be replaced by a violent craving for food. Ingestion of food, however, in such cases does not usually give the anticipated relief, and often brings on pain and induces vomiting. Irritability of the stomach may be extreme; on the other hand, it may be indicated by frequent eructations only. Under any circumstances, however, the taking of food or drink, except in moderation, will probably ensure its rejection and bring on epigastric pain. The vomit consists of ropy and tenacious mucus, mixed with matters which have been swallowed, and (if the vomiting have been prolonged) with bile. Blood in small quantities may be contained in it. The breath is febrile or offensive, and not unfrequently fetid. The eructations occasionally have the odour of sulphuretted hydrogen. Thirst is generally a marked feature, but now and then is wholly absent. The temperature is usually elevated above the normal, but rarely exceeds  $100^{\circ}$ ; it presents variations during the day, and, for the most part, an afternoon or evening rise. The patient often feels chilly, and even has distinct rigors. The skin is hot, but disposed to be moist at times. In most cases the tongue becomes covered early with a thick whitish or brownish creamy fur, through which the congested fungiform papillæ protrude; but it may be abnormally red and clean, and then often dry, glazed, and fissured. In some cases it is little changed from the normal. Taste is usually perverted; and there is often a sensation of bitterness or a metallic flavour. Headache is usually very severe, of an aching or throbbing character, and limited to some particular region. In some cases it is difficult, if not impossible, to distinguish it from that of megrim. Chiefly when the headache is frontal there is disturbance of vision and photophobia. The patient is commonly more or less irritable

and restless, yet depressed; he is often drowsy, yet unable to obtain refreshing sleep—his rest being disturbed by dreams. Further, the action of the heart frequently becomes enfeebled, the pulse quick and small, the extremities cold; and there may be palpitation, faintness, dyspnoea, and confusion of mind. Associated with gastric inflammation there is often disturbance of the bowels, generally flatulence, and either constipation, griping and purging, or irregularity of action. These disturbances, however, are in many cases due to concurrent inflammatory implication of the mucous membrane of the bowels.

In some cases the symptoms of the milder forms of acute gastritis scarcely differ from those of enteric fever; while in some they are little more than such as constitute an ordinary sick-headache; and in others amount collectively only to that vague sense of illness to which the term 'malaise' is commonly applied. In young children, drowsiness and other cerebral phenomena, such as coma and convulsions, are not unfrequent accompaniments of the gastric disorder: and it is among them that diarrhoea is chiefly common. When gastritis arises in the course of other affections its symptoms are liable to be overlooked.

3. The symptoms of chronic gastritis necessarily present a considerable resemblance to those of the acute disorder, but are on the whole more vague, and merge into those included in the collective term dyspepsia. The patient, moreover, is in many cases liable to remissions, during which he appears to enjoy comparatively good health. In other cases he ails continuously. Febrile symptoms, on the whole, are slight, and often altogether absent; thirst, anorexia, vomiting, and uneasiness or pain in the epigastrium and between the shoulders, are all more variable and generally less severe than in the acute disorder; vomiting, however, of an abundance of glairy mucus is often a characteristic phenomenon; the tongue varies in its condition, as it does in the acute affection, and often gets furrowed or intersected with fissure-like depressions; the breath is offensive; the bowels usually are confined; and the patient becomes restless, irritable, nervous, and hypochondriacal, but rarely suffers so severely from headache as those who labour under the most acute disorder. With its continuance emaciation and debility come on, with defective circulation, coldness of extremities, and tendency to palpitation and faintness. Numberless other symptoms and consequences of more or less importance are commonly, and no doubt in the main correctly, attributed to chronic gastritis. For the most part, however, they constitute no essential part of it, and are connected with it only as they are with many other affections in which the processes of nutrition are profoundly involved.

*Treatment.*—1. In the treatment of severe acute gastritis local measures are of great importance. Leeches (twelve, twenty, or more) may be applied to the epigastrium; or warm fomentations may be employed, or ice, or mustard poultices and other counter-irritants. Which of these applications should be selected must depend on the severity, or stage, or other conditions affecting the case. The irritability of the stomach

renders the introduction of food and medicine in bulk into that organ impossible or undesirable. A little ice may be sucked, or ice-cold water or milk sipped; and opiates in large doses should be administered. If given by the mouth they should be in the form of pill, powder, solution of morphia, or undilute liquid extract of opium. The association of opium with bismuth or magnesia is often very efficacious. The best mode, however, of introducing opiates is undoubtedly by subcutaneous injection.

2. In less severe cases, local bleeding need scarcely ever be resorted to, but warm fomentations and counter-irritants are of benefit. Here also the use of ice, or minute quantities of ice-cold water, often affords much relief. And generally it is desirable to avoid as far as possible the administration of food or drink until irritability and pain have in great measure subsided. In some cases opium is of great value; but generally it is not called for. Bismuth, magnesia, lime-water, nitrate of silver, effervescent alkalies, and hydrocyanic acid are often very beneficial. When constipation is present, or there is evidence of implication of the bowels, purgatives are valuable, especially perhaps castor oil, calomel in combination with rhubarb, and enemata. When food is given it should be of light quality and easily digestible. Milk and farinaceous substances are most suitable. Later on, animal broths, fish and chicken, may be allowed. Alcoholic drinks are not desirable, unless there be marked tendency to depression or collapse. Under similar circumstances ammonia is often serviceable.

3. Chronic gastritis usually requires much attention to hygienic conditions. The patient should be enjoined to take moderate and regulated exercise, to seek change of air and scene, to keep good hours, and generally to adopt such a mode of life and such habits as are conducive to health. The diet should be strictly regulated, but it is difficult to lay down definite rules with respect to such regulation. The patient's own experience is usually an important, if not the best, guide. He should carefully avoid all those articles of diet which he has found to be prejudicial to him, however wholesome theoretically we may suppose them to be. Milk, well-cooked farinaceous substances, fish, fowl, and well-roasted mutton and beef in small quantities, are probably on the whole the most suitable. Pounded raw beef is often well borne. Salted meats, rich and highly seasoned dishes, pork and veal, should be especially eschewed. Tea often disagrees. Alcohol is seldom beneficial, and should only be used sparingly and in a dilute form. The particular beverage to be employed must depend on circumstances. As to medicinal treatment, the bowels should be regulated by occasional laxatives or mild purgatives; and tonics (especially quinine or nux vomica in combination with hydrochloric acid, and calumba or gentian associated with alkalies and rhubarb, or bismuth) effervescing medicines, lime, silver, zinc, hydrocyanic acid, belladonna, opium, and pepsine, have all been found more or less useful under different circumstances and in different cases.

## III. ENTERITIS

*Causation.*—Acute inflammation of the bowels, like the corresponding affection of the stomach, presents every degree of severity. The simplest, or catarrhal, form may be caused by the local action of irritating ingesta, or those external conditions which are commonly instrumental in exciting idiopathic inflammations. Young children, mainly about the time of teething, are specially liable to it; and it is said to be common in scarlatina and other specific fevers. Occasionally it becomes chronic, and is then apt to be associated with morbid states of other organs, to which indeed it is often secondary. The stomach especially, under these circumstances, is frequently the seat of some chronic morbid process. But enteritis in the usual sense of the term (the ‘phlegmonous enteritis’ of Cullen) is rarely of idiopathic origin: it is generally the result of some mechanical injury, and thus complicates strangulated hernia, intussusception, the impaction of gall-stones and other foreign bodies, and intestinal stricture.

*Morbid Anatomy.*—1. Acute catarrhal inflammation of the bowels is characterised anatomically by congestion, tumefaction, and dryness of the mucous membrane, speedily followed by the more or less abundant secretion of mucus, which is ropy or watery, irritating, and sometimes mixed with blood. When the inflammation assumes a chronic form the mucous membrane becomes condensed and hardened, congested, and studded with black pigmentary deposits. There is often atrophy of the Lieberkühnian follicles, with granular or fatty degeneration of their epithelial contents; and atrophy, or even enlargement, of the solitary and agminated glands.

2. Occasionally, under conditions which are not well understood, membranous pellicles in patches arise, especially in the large intestine, in connection with chronic enteritis. They consist of corpuscular elements cemented together by a coagulable exudation, and are for the most part prolonged by rootlets into the Lieberkühnian follicles. Their development usually is attended with much greater congestion and thickening of the mucous membrane than is the simple catarrhal affection, and not unfrequently hemorrhage, suppuration, or gangrene ensues. In the large intestine the pellicular inflammatory patches are sometimes linear, sometimes irregularly polygonal or stellate, and occupy, for the most part, the prominent ridges of the mucous membrane, especially the ridges of the intersaccular constrictions. In some cases, while still occupying the more prominent parts, they form a coarse irregular network over large tracts of surface; in other cases they coalesce into uniform patches of considerable extent. In the small intestine pellicular inflammation may be found, either affecting only the free edges of the valvulae conniventes, or spread over large areas. Cases sometimes come under observation in which patients pass per anum shreds of false membrane, or even membranous

casts of the bowel, of soft texture, various thickness, and a dirty greenish or brown hue. This discharge is generally, if not always, the consequence of dysenteric ulceration.

3. The morbid changes discoverable after death in phlegmonous enteritis are such as are produced by intense inflammation of a limited tract of bowel. The affected part, which is mostly in the small intestine, and may vary in length from an inch or two to two or three feet, is as a rule much dilated. Its serous surface presents a general dusky red, slaty, or purplish black colour, due to the condition of the parts internal to it; it is marked, too, by lines or patches of more or less intense superficial congestion, may present blotches of subserous extravasation, and is often covered to a greater or less extent with adherent lymph. Its mucous and submucous tissues are mostly somewhat thickened and softened, sometimes only moderately congested, but presenting spots and streaks of extravasation, sometimes black from combined congestion and escape of blood, sometimes pale and infiltrated with lymph or pus, sometimes distinctly gangrenous. And its middle coat, sharing in these changes, is also more or less swollen and soft, congested or œdematous, or the seat of some form of inflammatory exudation. The inflamed tract usually presents fairly well-defined limits, terminating abruptly below in pale and healthy but contracted and nearly empty bowel, above in bowel which may also be healthy, but is dilated like the diseased portion, and filled, like it, with fecal contents. The diseased intestine frequently contains, in addition to fecal matter, sanguineous exudation, or a thick pitchy fetid fluid; and traces of the same may often be discovered in the contracted bowel below.

*Symptoms and progress.*—1. Catarrh may affect the lower bowel only, causing mild dysenteric symptoms; but very often it begins in the upper bowel, or stomach, and spreading thence downwards gradually traverses the whole length of the intestinal canal, causing in its progress uneasiness, aching, and griping—frequently attended with nausea and sickness while the inflammation is still high up, with diarrhœa and expulsive pains and efforts when it reaches the large intestines. The tongue generally is more or less furred and dry, the breath offensive, and the appetite impaired; but these symptoms vary, and are often absent, especially when the large intestine alone is affected. Some degree of general febrile disturbance, indicated by heat and dryness of skin, sense of chilliness, increased frequency of pulse, lassitude and headache, is usually attendant on the local disorder. In children, in whom inflammatory affection of the gastrointestinal mucous membrane is sometimes associated with aphthæ, the disease not unfrequently causes serious results and death, either from the debility which follows persistent diarrhœa and vomiting, or from the supervention of convulsions and coma. It is obvious that the symptoms of this disorder differ but little from those assigned to the commoner varieties of gastritis; but gastritis and enteritis are usually associated, and their respective characteristics consequently get intermingled.

The symptoms of the chronic disorder vary greatly, but may be briefly

summarised as combining, in various proportions, imperfect digestion of the alimentary matters received into the intestine, excessive secretion of watery mucus, increased peristalsis with griping pains, looseness of the bowels, discharge of watery, yeasty, or otherwise unhealthy and offensive evacuations, and innutrition from imperfect absorption of food.

2. The symptoms which attend enteritis with the formation of membranous pellicles are not special; they vary, on the one hand, between those of diarrhoea and dysentery, and, on the other hand, between those of mere colic and typical enteritis; moreover, the affection is often overlooked from the fact that it is apt to occur as a complication of the later stages of many grave disorders, as, for example, acute pneumonia, Bright's disease, cirrhosis of the liver, and cerebral affections.

3. The symptoms of phlegmonous enteritis are, even when the disease is unattended with any of the mechanical lesions which so often complicate it, liable to considerable variety—the variations depending mainly on the degree of inflammation and its extent, and on the situation of the affected portion of bowel. The principal factors in producing the characteristic symptoms are inflammation, on which the various febrile phenomena depend; and paralysis of the inflamed tract of bowel, which permits of its passive dilatation by the accumulation of its contents, opposes a more or less complete bar to their transit, and thus induces, on the one hand constipation, on the other vomiting.

Heat of skin, rigors, and quickness and hardness of pulse, not unfrequently mark the onset of the attack; but the invasion is in many cases insidious and unattended with obvious febrile symptoms. There is mostly some dryness and clamminess of the mouth, if not absolute thirst; and the tongue, which is occasionally pretty clean at the beginning, generally soon gets thickly coated, and ultimately dry.

A special feature of enteritis is the association of the abdominal pain and tenderness of peritonitis with the tormina of colic. Pain and tenderness are certainly present in most cases, at least in the beginning, and in dependence upon them the dorsal decubitus so characteristic of peritoneal inflammation. They are sometimes, however, scarcely appreciable from first to last, and generally subside in the progress of the case. It can readily be understood that, when the peritoneal surface is largely involved, pain and tenderness will generally be proportionately severe; that when an extensive length of bowel is affected there will be correspondingly extensive uneasiness and tenderness; and that when, as sometimes happens, the serous surface is not inflamed, or the affected portion of bowel is small, pain and tenderness may be not only limited in extent, but no greater than we find them in colic or simple ulceration of the mucous membrane. It may be observed that limited pain and tenderness are very commonly referred to the region of the umbilicus. Tormina are often at the onset very agonising, and are then probably due in some measure to the spasmodic movements of the inflamed bowel; but they continue after paralysis is established, in consequence of the violent but ineffectual efforts of the bowel above to overcome the impediment which

the disease produces. But tormina are sometimes scarcely recognisable, and frequently, like pain, cease comparatively early.

Constipation and vomiting are among the most important symptoms of enteritis. Constipation, in the uncomplicated affection, is due simply to want of contractile power in the inflamed length of gut. It is therefore not necessarily absolute: there is no reason why the attack should commence with constipation, or why the bowel below the seat of disease should not empty itself in the progress of the case, or even why a certain amount of faecal matter should not slip through the inflamed region into the healthier bowel below. Nevertheless the inflamed bowel is really a substantial impediment, constipation is a striking incident in the disease, and purgatives as a rule fail to produce a purgative effect. The vomiting of enteritis is probably at the commencement mainly functional, but ultimately, it is due, like the constipation, to intestinal obstruction. In the first instance, no matter where the obstruction, the vomited matters are merely the secretions of the stomach mixed with alimentary substances; but soon bile is added, and before long glairy mucus and bile alone are discharged. Then the eructations become fetid, and the fluid brought up is turbid and brownish, and by degrees comes to resemble the contents of the lower part of the small intestine; but it becomes fetid also—far more fetid, indeed, than the contents of a healthy bowel ever are. This discharge of ‘stercoraceous’ matter by the mouth is due, not to inverted peristaltic action, but to the fact that the general contents of the distended bowel are gradually churned up, as it were, and intermingled, by the constantly recurring peristaltic movements of their muscular walls.

Hiccough is often a distressing symptom. Tympanites is probably always present; slight at the beginning, but increasing as the case progresses, until the belly becomes greatly distended, tense, and drum-like. It is due mainly to the distension of the inflamed bowel and that above it with faecal matter and flatus. But now and then it is connected with rupture of the distended intestine and escape of gas into the peritoneal cavity.

The pulse usually is accelerated and hard at the beginning, but varies in different cases in frequency, volume, and strength, and is sometimes nearly normal in character; but as the fatal issue approaches it gets more and more feeble, and sometimes at length wholly imperceptible at the wrist. It generally also becomes quicker, but sometimes slower, and not unfrequently irregular.

The temperature of the skin is usually in the first instance elevated, and the surface dry; but even then sweats are apt to break out, especially during the colicky paroxysms; subsequently the temperature falls, the extremities and face get cold and pale or livid, with sometimes a slight tinge of jaundice, and all parts of the surface bathed in profuse cold sweat. The internal temperature, however, often continues high to the last, notwithstanding the coldness of the extremities, and general coolness of the surface. The expression is generally indicative of anxiety and distress, and the features are pinched and shrivelled.

The patient as a rule retains his senses throughout his illness, and even up to the moment of death ; but this event is often preceded by a period of quiescence or lethargy, and occasionally by slight rambling and partial unconsciousness. There is generally almost complete suppression of urine.

Enteritis in its most violent form is an extremely dangerous, and indeed generally a very rapidly fatal, malady. Death may occur within twenty-four hours, and is rarely delayed beyond a week.

*Treatment.*—The treatment of the milder forms of enteritis is so intimately connected on the one hand with that of inflammatory affections of the stomach, and on the other with that of diarrhœa and dysentery, that the reader may be safely referred to the articles on those subjects for all necessary details. As regards the treatment of the more severe forms of the disease, two main principles seem to be fairly well established : namely, first, to relieve pain, and prevent as far as may be all movements of the bowels ; second, to avoid every attempt (at least until all grave symptoms have ceased) to force the bowels by the administration of purgatives. Constipation, lasting for a few days, or even prolonged for a week or two, in itself is generally a matter of very little consequence ; it is, however, a matter of very serious consequence to intensify the pain from which patients are already suffering, to fret and irritate inflamed organs, and to subject to unwonted violence bowels unnaturally soft, enfeebled, and ready to undergo laceration. Clearly, if patients are to get well, their recovery must in the first instance depend on the recovery by the diseased bowels of their healthy tone and capability of peristaltic action, and on the relief of pain and irritation. For these purposes, opium in large and frequent doses is generally our most valuable resource. No absolute rule can be laid down with regard to the quantity of this drug to be given at one time, or the frequency with which the dose should be repeated ; the patient should, however, be got well under its influence and kept under its influence. For many reasons it is best administered by subcutaneous injection.

But our treatment need not be limited to the use of opium. The abstraction of blood is often of the greatest value. This is most efficacious early in the disease, and may be effected either by the opening of a vein in the arm, or by the application of ten, twenty, or thirty leeches to the surface of the belly. Warm but light applications, and hot fomentations, generally soothe ; and sometimes mustard plasters and similar mild counter-irritants give relief. In the same way enemata of warm water or gruel are at times useful. To relieve nausea and vomiting, ice, hydrocyanic acid, alkalies, lime-water, bismuth, carminatives, and the like may be tried, and may be of much efficacy ; but when the vomiting is simply the consequence of over-distension of the bowels, as it sometimes is late in the disease, such remedies necessarily fail. The extreme prostration which so early manifests itself is a strong indication of the need of food and stimulants ; but their exhibition by the mouth tends to increase distension, already probably painful, and to promote sickness ; and under

such circumstances they are little likely to be absorbed. It is obvious, indeed, that alimentary matters, if given by the mouth, must be given in very small quantities, and in a form suitable for their ready absorption. They are best administered in the form of enemata.

#### IV. ULCERATION OF THE STOMACH<sup>1</sup>

*Causation.*—The occurrence of excoriation or superficial ulceration in the course of ordinary gastritis has already been referred to. Such lesions have rarely, however, any special importance, and as a rule speedily undergo spontaneous cure. But the stomach is also liable to become the seat of ulcers which tend to spread widely and deeply, are productive of serious symptoms and sometimes of death, and the origin of which is to some extent enshrouded in mystery. These ulcers are seldom observed before the age of ten or fifteen, but subsequently to that period they seem to increase in frequency with advanced life, not, indeed, absolutely, but in relation to the numbers of persons living at each successive period. They appear to be two or three times more common in females than in males. They are often associated with amenorrhœa and anæmia, or chlorosis, and in both sexes (but more especially in men) with the cachexiæ which follow from habits of drinking and dissipation, and from syphilis. It is possible that these conditions of the system may be the actual causes of the ulceration; it is more probable, however, that they tend to promote the spread and retard the healing of ulcers which have begun in the first instance independently of them. Virchow considers that ulcers originate mainly in affections of the vessels connected with the diseased area, especially embolism or degenerative change in the arteries, attended with arrest of circulation and necrosis, or obstruction of branches of the portal system of veins, followed by interstitial hemorrhage. But it seems not improbable that the superficial ulcers which form in gastritis, and which as a rule readily heal, may under certain circumstances remain open, and be irritated into active enlargement. The progressive spread, and unwillingness to heal, of gastric ulcers, are readily explained by the constant irritation to which they are subjected by the ingestion of food, the pouring out of gastric juice, and the movements of the stomach in digestion.

*Morbid anatomy.*—Gastric ulcers vary in size from that of a four-penny-piece up to that of the palm of the hand. The small ones are usually circular or oval in shape; the larger are more or less irregular, either from being formed by the coalescence of several smaller ulcers, or in consequence of irregular extension. When small an ulcer usually appears as if it had been made by punching out a bit of the mucous membrane. Its edges are more or less perpendicular; and the tissues entering into their formation are infiltrated, indurated, and probably thickened to some little distance around. Its floor may be smooth,

flocculent, or even superficially gangrenous ; and may be formed, according to the depth to which the ulcer has reached, by either the submucous tissue, the muscular coat, or simply the serous membrane. In an ulcer of large size the tissues which surround it are usually considerably thickened and indurated from inflammatory overgrowth, and often much congested ; the edges, which are specially thickened, usually slope downwards to the floor of the ulcer, which thus becomes smaller than the superficial area of ulceration ; sometimes, however, they are perpendicular ; sometimes undermined, and overhanging. The floor of a large ulcer may be formed like that of a small one by any of the gastric tunics except the mucous membrane itself ; but it may be formed also by the substance of the liver, pancreas, or any other organ or tissue which has become adherent to the stomach, and involved in the progress of the ulceration. The floor may be smooth, irregular, and flocculent, or sloughy, or may present granulation-like bodies due to the projection of the lobules of the eroded pancreas.

Gastric ulcers not unfrequently cicatrise. The surrounding thickening then diminishes, the sloping edges become undistinguishable, on the one side, from the contiguous mucous membrane, on the other from the floor of the ulcer. The ulcerated surface contracts, radiating puckers form, and the central raw area grows smaller and smaller, and at length heals. The result is an opaque, whitish, smooth, tough, depressed area, surrounded by more or less obvious radiating folds of mucous membrane, and often attended with marked and it may be serious deformity of the stomach. It is not uncommon to find ulcers partly healed, or cicatrising at one part while undergoing extension elsewhere.

Unfortunately gastric ulcers do not always heal. In many cases they remain quiescent ; in many they slowly extend ; in many they end in perforation. Perforation sometimes takes place at once into the peritoneum ; but sometimes the base of the ulcer previous to perforation becomes adherent to some neighbouring part, so that, while extravasation of the contents of the stomach into the peritoneal cavity is prevented, a communication becomes established with the transverse colon, or small intestine, with the pleura or lung through the diaphragm, or with the external air through the abdominal parietes. In other cases some artery (the splenic, coronary, gastro-epiploic, or one of their branches), or even the hepatic artery, or portal vein, becomes eroded, and profuse hemorrhage ensues.

Gastric ulcers are usually solitary, but occasionally two, three, or more are present at the same time. They may occur at any part of the stomach ; but are more frequent in the pyloric than in the cardiac half, in connection with the posterior than the anterior wall of the organ, and in the neighbourhood of the smaller than in that of the larger curvature. Perforation is believed to be relatively more frequent in females than in males ; and is a not uncommon termination of ulcer, especially in young women.

*Symptoms and progress.*—The symptoms which attend gastric ulcer

present much variety. In a few cases the disease proves fatal by perforation or hemorrhage without having ever been attended with symptoms to attract attention to the stomach as the seat of disease. In most cases, however, the patient suffers from dyspeptic phenomena, of which the most common and characteristic are pain, vomiting, and hæmatemesis. As ulcer of the stomach is mainly a chronic disease, so the symptoms to which it gives rise generally assume a chronic character. They creep on for the most part gradually, probably sometimes intermitting for a while, often presenting exacerbations, but, on the whole, tending to become more and more pronounced.

At first possibly the patient complains of distension, flatulence and uneasiness, especially after food, and of impairment of appetite; but soon the uneasiness becomes pain; and sickness presently supervenes. The pain varies somewhat in intensity and character. It usually begins in, and may remain limited to, the epigastrium, which becomes tender on pressure; or it is referred to the region of the spine corresponding to the last two or three dorsal and first two or three lumbar vertebræ, or to the interscapular region—the muscles on either side often being tender; or it occupies the umbilicus, or some other point or area in the neighbourhood; and generally, when it is severe, it radiates from its point of chief intensity, upwards towards the œsophagus, backwards to the loins, or downwards and laterally over the greater part of the abdominal cavity. The pain, when severe, is of a burning, boring, or shooting character, often attended with a sense of soreness; it is aggravated by taking food, and in some cases occurs only then. It usually comes on a few minutes after ingestion, but is occasionally delayed half an hour or an hour afterwards. It is doubtful how far the situation of the pain serves to indicate the situation of the ulcer; but both Dr. Budd and Dr. Brinton are inclined to believe that pain occurring chiefly in the pit of the stomach indicates the presence of an ulcer in the anterior wall of the stomach, and that pain in the back implies a corresponding situation for the ulcer. Further, Dr. Brinton regards the decubitus of the patient as suggestive in this respect—the patient lying as a rule on that aspect of the body which is farthest removed from the seat of ulceration.

Vomiting may be absent from first to last; it usually comes on, however, during the progress of the case, for the most part subsequently to the pain; and is then very persistent. The attacks are determined by the taking of food, usually come on a little later than the pain, and not unfrequently by emptying the stomach cause the pain to subside. The vomiting may be attended with violent spasmodic efforts, or may be effected in the manner of simple regurgitation. Hemorrhage is a frequent consequence of gastric ulcer—taking place sometimes from the congested mucous membrane which bounds it, sometimes from the general surface of the ulcer, sometimes from a vessel which has undergone erosion. In the last case especially the bleeding is apt to be very profuse, and to be repeated from time to time; and consequently large quantities of blood are vomited and subsequently passed by stool.

The long continuance of dyspeptic symptoms, with pain induced by taking food and having the characters which have been described, and with vomiting coming on pretty constantly at some variable period after ingestion, is alone strong presumptive evidence of the presence of a gastric ulcer. And if to these be added the occurrence of profuse hæmatemesis or melæna, there can be little room for doubt.

The most frequent termination of gastric ulcer is no doubt in convalescence. There is, however, a great tendency for healed ulcers to break out again, and consequently for patients who seem cured to have relapses. When the disease ends fatally death may be due to simple asthenia—the patient sinking, worn out by the combination of long-continued pain, vomiting, and want of food; or it may be caused by the sudden loss of a large quantity of blood, or by the repetition, at longer or shorter intervals, of smaller but still copious hemorrhages; or it may result from perforation. When perforation takes place into the peritoneal cavity, sudden intense abdominal pain and collapse occur, speedily followed by general peritonitis; and the patient usually dies in from five or six hours to two or three days after the occurrence of the accident. When, however, perforation takes place into any of the hollow viscera or other cavities than that of the peritoneum, the symptoms which arise are usually much less sudden and grave, though still in many cases leading sooner or later to a fatal result.

*Treatment.*—Attention to diet is of the utmost importance in the treatment of gastric ulcer. The patient must be nourished; and yet all the digestive actions of the stomach are inimical to the cure of the lesion. We must consequently be especially careful as far as possible to avoid overloading the stomach or causing gastric pain, or uneasiness, or vomiting. With this object it is important to administer as little food as is compatible with the maintenance of life, and to give it in small quantities at a time, and at short intervals; it is important also to select food of such a kind as will impart nourishment without causing undue irritation of the stomach; and, in reference to this matter, it may be observed that few articles of diet are so suitable as milk, which may be thickened, if necessary, with biscuit powder, arrowroot, or similar substances. Milk, however, sometimes disagrees, and then recourse must be had either to farinaceous substances mixed with water, or to animal broths and jellies. Pounded raw beef flavoured with sugar or currant-jelly may be employed in some cases with great advantage. Liquids are generally ill borne when hot; and hence it is usually best to administer them tepid or cold. Hot tea and coffee especially are injurious. As the case progresses towards recovery eggs may be given, and tender, easily digested, meats. Alcoholic stimulants should, if possible, be avoided; if given, they should be in a diluted form and cold. In some cases it is necessary to feed the patient for a time by means of nutrient enemata only. The chief medicinal agents which have been employed for the cure of ulcers are nitrate of silver, bismuth, the carbonated alkalies, and opium. It is certain that the combination of bismuth, in doses varying from ten to twenty grains, with opium is often very efficacious in relieving pain and vomiting, and

apparently in promoting the cure of the ulcer. Iron and the vegetable tonics are indicated when the more distressing symptoms have been relieved and the patient seems convalescent. When hemorrhage or any other serious complication occurs, special measures will be needed.

Counter-irritation and other external treatment applied to the epigastrium are often serviceable.

---

## V. ULCERATION OF THE BOWELS

*Causation and morbid anatomy.*—1. Intestinal ulcers are much more common, and various in character, than those of the stomach. Their causes for the most part are equally obscure. In many cases, no doubt, simple inflammation of the mucous membrane is followed by excoriation; which either rapidly heals and gets effaced, or, in consequence of continued irritation, becomes a veritable ulcer. Such ulcers may arise from simple mechanical irritation. They are rounded or irregular in form, vary in size, and present congested and well-defined margins, and irregularly excavated shreddy greyish surfaces. The margins and the surrounding tissues are in some cases considerably thickened and indurated, in others present little obvious departure from the normal state. Ulcers of this kind are not unfrequently met with in the duodenum, and in many cases are not improbably due to the same causes (whatever they may be) as the so-called 'chronic ulcers' of the stomach. They are also occasionally met with here apparently as the result of extensive superficial burns. The large intestine, however, is their most common seat; and they are produced here for the most part by the mechanical irritation of retained fæces or intestinal concretions. They are often found in the cæcum and its appendage, where such accumulations are very apt to form; but they may be developed at any part of the larger bowel. In cases of long retention of fæces, whether from simple constipation or from stricture, it is not rare to find the mucous surface studded with tracts, varying from one to many square inches in area, and consisting of groups of circular ulcers, from half an inch in diameter downwards, separated from one another by a network of congested and partly undermined bands of mucous membrane. Again, such ulcers may arise in any part of the intestine, whether large or small, from the effects of the passage or impaction of gall-stones or other solid bodies, especially when impaction occurs above a stricture or other such impediment.

2. In other cases ulceration is connected with the formation of a membranous pellicle; a linear, stellate, or irregularly polygonal patch of mucous membrane becomes congested and swollen, and soon covered with an opaque whitish or buff-coloured exudation, which is friable and granular, and extends by rootlets into the Lieberkühnian follicles. This, after a time, separates, leaving sometimes a sound surface, sometimes a slight excoriation, or even a distinct ulcer, with a greyish or yellowish floor and a well-marked margin of congestion. These ulcers may be met with in any part

of the bowel, but are much more common in the large than elsewhere. In the small intestine they affect chiefly the free edges of the valvulæ conniventes; in the large, either the projecting ridges formed by the intervals between the sacculi, or those corresponding to the longitudinal muscular bands. Sometimes we find extensive tracts of congested bowel studded or intersected with patches or bands of membranous exudation, or consecutive ulceration, or both intermingled. This condition is met with under various circumstances: especially perhaps in pneumonia, and many chronic affections, such as Bright's disease, cirrhosis of the liver, cancer, and chronic phthisis.

3. Sometimes ulcers originate in foci of submucous suppuration, as occurs in pyæmia, or in patches of deep-seated sloughing like ordinary boils. Among the latter may perhaps be reckoned the ulcerative inflammation of the follicles of the colon, which Rokitansky describes, and is believed to constitute the early stage of dysentery. The follicles enlarge to the size of a tare or pea, become surrounded by a halo of congestion, and then undergoing suppuration form each an ulcerated opening, which eventually enlarges and constitutes a circular ulcer, with overlapping edges.

4. Ulceration may be due to the formation and detachment of a superficial slough. Circumscribed patches of intense congestion or extravasation appear in the substance of the mucous membrane, which, shortly dying, come away bit by bit, or in mass. The above process is often effected with little obvious change in the immediately surrounding parts, and the resulting pits are for the most part speedily effaced. This affection is not uncommon in small-pox, typhus, and other such diseases. It frequently involves only the valvulæ conniventes, or the corresponding projections of the large intestine. It may be due to sudden arterial obstruction.

5. But sloughing, to a much more serious extent, is sometimes met with, especially in the large intestine: patches of mucous membrane become livid, brown, or nearly black with congestion; and their central areæ assume a grey or ashy colour, get shrunken, depressed, and softened, and break down into a soft, shreddy substance, which partly becomes detached, and partly adheres to the floors of the excavations and to their not yet broken-down edges. The process tends to spread.

It is not pretended that all non-specific ulcers arise in one or other of the modes here enumerated, or that they necessarily maintain in their ulterior progress the distinctive characters of their origin. Yet, independently of their exciting causes and early peculiarities, all ulcers are apt after a time to present certain common varieties of appearance, dependent mainly on the processes which are actually taking place in them. Thus, when they are healing, we find the general surface smooth and clean or granulating, the edges little thickened or congested, perhaps puckered, and probably sloping to the ulcerated area, with which they are in fact continuous; when they are sluggish, the edges are tumid and rounded, probably overhanging, and the general surface smooth; when they are spreading, the surrounding mucous membrane presents more or less in-

tense congestion and swelling, and the immediate margin is either flocculent and ash-coloured, or presents a vivid red, raw, bleeding wall, or forms a ring of distinct gangrene, and the floor is irregular and flocculent. The base of an intestinal ulcer is generally constituted by the submucous tissue, but not unfrequently the transverse muscular fibres are exposed; and when an ulcer tends to perforate the bowel the muscular coat itself becomes opaque, softened, and in part destroyed.

The above account applies mainly to individual ulcers. But very often, and much oftener in the large than in the small intestine, many ulcers are present at the same time, and tend to increase either in number or in size or in both of these respects, and to coalesce. And then, according to the stage to which the lesion has advanced, we meet in different cases with either a number of ulcers separated from one another by an imperfect network of mucous membrane; or interlacing networks of ulceration and mucous membrane; or islets of mucous membrane in an expanse of ulceration; or, lastly, extensive tracts from which the mucous coat has been wholly removed. In these cases the transverse muscular fibres are often freely exposed, and the remains of mucous membrane are red, swollen, and rounded, and in the form of tubercle-like excrescences. The affected bowel, moreover, is frequently much contracted, and the muscular walls hypertrophied.

This is not the place to discuss the important subject of specific ulceration of the bowels. Yet specific ulcers constitute by far the most formidable class of intestinal ulcers. The more important of them are the following:—First, syphilitic ulcers: these have not been certainly recognised in the alimentary canal excepting in the neighbourhood of its inlet and outlet; syphilitic ulceration of the rectum is a well-recognised, and for the most part very intractable, lesion. Second, the ulcers of enteric fever: these affect mainly Peyer's patches, and are most abundant and large in the lower part of the ileum; they not unfrequently involve also the solitary glands of the large intestine, especially in its upper part. Third, tubercular ulcers, which originate for the most part in the same glands and situations as enteric-fever ulcers. And, fourth, the various kinds of ulcer due to the breaking down of carcinoma and other varieties of malignant disease.

Many intestinal ulcers cicatrise and leave behind them little or no trace of their existence. In other cases, however, and indeed in a large proportion of them, results of more or less serious importance follow. Sometimes, as we see in the rectum, when a vast continuous surface has been destroyed, the wound never heals; and, even in cases where the destruction has been much more limited, the ulcer may assume the characters so often presented by chronic ulcer of the stomach, and be ready, if it cicatrises, to break out again and again. But generally, when a large ulcer heals wholly or in part, especially if it has involved the whole circumference of the bowel, some degree of contraction of the bowel, or stricture, results. In many cases hemorrhage takes place either from the congested surfaces or margins of ulcers, or from vessels perforated in their progress; and such hemorrhage

may be so frequently repeated, or so abundant, as to prove fatal. In many cases, also, perforation of the bowel takes place. This accident is usually due to a sudden tear in the floor of an ulcer, which has got unusually thin, and undergone softening, or become weakened in some other way; and not unfrequently depends immediately on some violence inflicted from without, or some undue pressure from within, such as may result from over-distension, or violent peristaltic movement. The rupture usually takes place at once into the peritoneal cavity, causing extravasation of fecal matter and generally fatal peritonitis. But not unfrequently inflammation arises on the peritoneal aspect of the ulcerated bowel; adhesion takes place between it and some neighbouring viscus; and consequently the threatened perforation becomes, for a time at least, averted. In many cases, a communication becomes established between the bowel and some neighbouring hollow organ—a result preceded either by the formation of adhesions or by the development of a circumscribed abscess between the two organs. The latter mode of communication is especially liable to take place when the ulcer opens on the mesenteric aspect of the small intestine, or in the corresponding part of the larger bowel, and consequently into the connective tissue, with which the bowel is in these situations closely invested. Thus, we occasionally find contiguous portions of the small intestine communicating with one another, or the small intestine with the transverse or some other part of the colon; the rectum, sigmoid flexure, or ileum with an ovarian cyst, the urinary bladder, or vagina; the duodenum or transverse colon with the gall-bladder; the stomach with the transverse colon; or lastly, almost any part of the intestinal canal with the external surface.

*Symptoms and progress.*—The symptoms of ulceration of the bowels are so constantly associated with those of the different morbid states of the system on which it depends, or those due to the various complications which follow upon it, that we seldom have the opportunity of studying them in their simple form. It may be stated generally: that ulceration of the bowels is often attended with febrile symptoms, which assume, if the disease becomes chronic, a distinctly hectic character; that the affected bowel is often tender on pressure—a characteristic which is especially observable if the ulceration be extensive, or occupy the cæcum or some other part of the large intestine; that there is almost necessarily some impairment of nutrition marked by emaciation, debility, and feebleness of circulation; that there is more or less abdominal soreness, aching, or griping; and that, above all, there is something abnormal in the action of the bowels and in the evacuations. The symptoms will vary according to the seat of disease. If the ulcer be high up, and especially if it be in the duodenum, the symptoms will approximate to those of gastric ulcer; there will probably be pain coming on some time after food, and vomiting, but no material interference with the function of defæcation. If the ulceration occupy the central portion of the small intestine, there may be nothing beyond gradually increasing emaciation, and occasionally colicky pains, to indicate that the bowels are affected;

and indeed extensive ulceration may be present even in the lower part of the ileum without occasioning any obvious modification of the stools; there may, indeed, be constipation from first to last. Usually, however, if there be ulceration in the last-named situation, and especially if the large intestine be involved, diarrhœa may be looked for. The stools are then generally liquid, and contain an abnormal quantity of the fluid secretions of the bowels, and not unfrequently blood; they are, moreover, often peasoup-like in colour and consistence, and more offensive than in health; further, they are usually passed much more frequently than natural, and the patient suffers from frequent colicky pains and tenesmus. As the ulceration approaches nearer and nearer to the lower part of the large intestine, the evacuations assume more and more of the so-called 'dysenteric' character. They are then passed with extreme frequency and great tenesmus; are scanty, mucous, often sanguinolent, and not unfrequently entirely free from true fæcal matter. The latter may be only passed occasionally in small hard lumps, invested in mucus; indeed, constipation, so far as regards the passage of fæcal matter, is often one of the most troublesome and distressing symptoms of ulceration of the rectum and lower part of the colon. It is in the dysenteric form of the disease, moreover, that the evacuations become most offensive, the fetor sometimes being putrid and almost insufferable. Besides the slight oozing of blood which tinges the evacuations in dysenteric diarrhœa, hemorrhage to a considerable amount sometimes takes place; and this may be either continuous or recurrent, and sufficient to destroy life. Many of the communications which have been described as taking place between the intestine and other organs as a result of ulceration are doubtless of little practical importance; but some are dangerous, or present features of clinical interest. Among the latter may be especially mentioned: communications between the stomach or duodenum and the colon, which lead to the occasional or constant vomiting of actual fæces and to the escape of undigested food into the large intestine; and communications with the urinary bladder, which occasion the escape of flatus and fæces into that viscus, with other consequences which are easy to imagine. Rupture into the peritoneum generally causes fatal peritonitis.

*Treatment.*—Our aims in treating ulcers of the bowels should be: first, to promote the healing of the ulcers and prevent as far as possible the local mischances which are apt to follow; second, to check abdominal discomfort and diarrhœa; and, third, to support the patient's strength. It is of course doubtful how far remedies given by the mouth can act locally on ulcers low down in the bowel, and how far, therefore, substances like bismuth, nitrate of silver, iron, copper, mineral acids, and the like can promote cicatrisation; still they are often employed with this object, and sometimes apparently with benefit. But it is of great importance that the bowels should be kept at rest, and violent peristaltic movement as far as possible restrained. Purgatives, therefore, should be in a great measure, or wholly, eschewed, while astringent medicines (iron, copper, lime, chalk,

tannic acid, or vegetable astringents) will probably prove serviceable. Opium is especially valuable; and the compound kino powder and the combination of aromatic chalk powder with opium are useful preparations. It is important, however, to note that opium cannot always be taken in these cases; for chronic ulceration of the bowels is often attended with an irritable state of the mucous membrane of the mouth and stomach which the use of opium is apt to augment. If this drug cannot be employed, it may be replaced to some extent by other sedatives, such as hyoseyamus, belladonna, Indian hemp, or hydrocyanic acid. Opium may often be given with advantage in the form of enema or suppository. It is obvious that the various measures which have just been enumerated, while they check peristalsis, act with equal efficacy in fulfilling the second indication of treatment—namely, the arrest of diarrhœa. The maintenance of the patient's strength must be effected by the use of tonic medicines and the careful administration of suitable food and stimulants. The form of tonic must be adapted to the special requirements of the case, and to the other details of treatment it may be considered necessary to adopt. As regards food, this should be well cooked, well masticated, easy of digestion, given in moderate quantities, and at regular if not frequent intervals. Farinaceous foods are in many cases most suitable; but eggs, fish, and fowl may often be used with advantage. Butcher's meat is sometimes wholly inadmissible.

## VI. PERFORATING ULCERS OF THE CÆCUM AND RECTUM

### (*Typhlitis, Perityphlitis, and Periproctitis*)

There are certain parts of the bowels which are especially liable to become the seat of non-specific forms of inflammation and ulceration, or to be involved in inflammation originating in their neighbourhood: these are the duodenum and the large intestine—more particularly the cæcum and lower part of the rectum.

As to the duodenum, we have already pointed out that it is not unfrequently the seat of ulcers, which resemble chronic ulcers of the stomach, and of ulcers arising in connection with extensive burns of the skin. We may add that from its situation and attachments it is liable to become perforated from without by abscesses of the gall-bladder and liver, and by abscesses originating, no matter how, in the upper part of the retro-peritoneal tissue.

So, also, the large intestine, from its peculiar relations with the peritoneum, and from the extent to which it is in many places devoid of peritoneal covering, and continuous, therefore, with the sub-peritoneal connective tissue, and thus brought into almost immediate connection with the various organs lying beneath the parietal peritoneum, is peculiarly apt to be involved in extraneous inflammation and suppuration. For similar reasons (at least in great measure) inflammation originating here is liable to induce inflammatory thickening and abscess in the surrounding tissues.

*A. Typhlitis. Perityphlitis*

*Causation and morbid anatomy.*—The terms ‘typhlitis’ and ‘perityphlitis’ (the former signifying inflammation of the walls of the cæcum, the latter inflammation of the tissues surrounding it) are commonly employed in reference to those cases in which inflammation of the cæcum or its vermiform appendage involves, either by perforation or by simple extension, the connective tissue of the iliac fossa or the peritoneal cavity. Ulceration of these parts very frequently takes place (in enteric fever and phthisis to wit) without causing the special phenomena of typhlitis. There is reason, indeed, to believe that in most, if not all, cases where inflammation spreads from the cæcum to the surrounding tissues, its spread is referrible to ulcerative perforation. The causes of the lesion in question are no doubt various. It may be due to the presence of malignant disease, to the extension of tubercular, typhoid, or dysenteric ulcers, to simple but extreme distension of the cæcum, to the fretting of its surface by accumulated faecal contents, to the mechanical effects of bristles, pins, or bits of bone which have been accidentally swallowed, or to the lodgment of intestinal concretions.

Concretions are mostly found in the vermiform appendage, and are the usual causes of perforative ulceration of this part. They vary from the size of a pea to that of a date-stone, are sometimes of a waxy consistence and lustre, sometimes brown, opaque, laminated, and for the most part faecal, sometimes composed mainly of earthy phosphates, but consist in all cases of an admixture in unequal proportions of ordinary faecal matters and the secretions from the mucous surface, and are occasionally developed around small extraneous bodies.

There is no doubt that practically the great majority of cases of typhlitis are cases of perforative ulceration of the vermiform appendage due to the presence of concretions therein and the irritation caused by them. In most cases the perforation is small, the escape of faecal matter insignificant, and circumscribed peritonitis, or peritonitis limited to the neighbourhood of the cæcum alone, ensues. In many such cases the inflammatory swelling thus induced gradually subsides. Often, however, an abscess forms which enlarges more or less rapidly, and then extends in a direction determined in great measure by accidental circumstances: in one case descending into the pelvis and opening into the rectum; in another passing out with the pyriformis muscle and presenting in or below the buttock; in another running along the inguinal canal into the scrotum, or along the psoas and iliacus muscles into the upper part of the thigh; in another forming a swelling in the groin immediately above Poupart’s ligament, and possibly diffusing itself over a wide area between the abdominal muscles. In most cases no doubt it presents itself in the iliac region superficial to the position which the cæcum normally occupies. An abscess of this kind may get cured by discharging its contents either into the cæcum itself, or at any one of the spots which have been enumerated; or, burrowing extensively, it may form a sinus or series of sinuses which are

never obliterated. The communication between the abscess and cæcum is sometimes maintained; at other times it closes more or less speedily, and the abscess appears henceforth to be independent of the bowel. In other cases rupture takes place directly into the peritoneal cavity, and fatal peritonitis is excited. Circumscribed abscesses themselves may rupture ultimately into the peritoneum.

*Symptoms and progress.*—Typhlitis taking its origin from the vermiform appendage is a disease mainly of early life, and occurs more frequently in males than in females. Its symptoms are, in the first instance, pain, tenderness, and swelling in the region of the cæcum, together with signs of inflammatory fever, and sometimes rigors. The local symptoms are for the most part those which may be caused by inflammation of whatever origin occupying the venter of the ileum. If an abscess forms, but extends downwards into the pelvis, or remains deep-seated, the case is naturally obscure. If, however, it tends to point anteriorly, the fulness and hardness get more and more pronounced, and gradually develop into a fluctuating hemispherical protuberance over which the integuments become oedematous and congested. Sometimes, even at this stage, the swelling gradually subsides and disappears, owing to the abscess having discharged itself into the bowel; but more frequently it still enlarges and ultimately opens externally, discharging a greater or less amount of fetid pus, sometimes having a fæcal odour, sometimes containing fæcal matter and bubbles of gas. The further progress of the case may be towards either recovery, or the formation of successive abscesses or fistulæ, or the establishment of an artificial anus. When peritonitis arises from perforation, its occurrence may be quite sudden and unpreceded by any form of premonitory symptoms; but generally it is heralded by localised uneasiness or pain, or (as we have pointed out) supervenes in the course of well-marked perityphlitis.

The functions of the alimentary canal are by no means necessarily disturbed to any great extent in typhlitis. Sickness is often absent. Constipation is not unfrequently present during the early period of the disease; while diarrhœa is apt to supervene at a later stage. But none of these symptoms has any particular uniformity or value. It may be remarked that, from the close proximity of the cæcum to important veins and nerves, typhlitis is apt to induce painful neuralgic symptoms and oedema of the right lower extremity. Its duration is necessarily very uncertain. Sometimes the patient speedily recovers, sometimes he lingers indefinitely with a constantly discharging abscess or a succession of abscesses. If, however, perforation take place into the peritoneum, death, for the most part, rapidly follows. It is important to bear in mind that those who have once suffered from typhlitis are liable to recurrences of the disease, and that fatal peritonitis may ensue on any such attack.

Although inflammation beginning in the cæcum is a very common and important cause of inflammatory swelling and suppuration in the right iliac fossa, it must not be forgotten that this part is also a common seat of inflammation and abscess from other causes, and further, that such

abscesses are liable to form communications with the cæcum, and hence still further to simulate primary typhlitis. Among the affections here referred to may be enumerated: inflammation of the ovary and connective tissue in its neighbourhood; idiopathic abscesses of the venter ilii, or in the course of the psoas muscle; psoas abscess from caries of the spine; renal abscess; and all descending retro-peritoneal abscesses, whether from the interior of the spinal canal, the pleura, lung, or liver.

*Treatment.*—The medical treatment of typhlitis is in principle, and indeed in most of its details, the same as that of enteritis and other forms of intestinal ulceration. It consists mainly in keeping the bowels quiet by the aid of opium, and in the use of local applications. It is almost more important in typhlitis than in any other affection to avoid opening medicines: for, especially if the disease be in the appendage, rupture into the peritoneum is in many cases prevented solely by slight adhesions. This danger often continues, indeed, for some time after the local inflammation seems to have subsided; and caution, therefore, should be exercised in respect of the use of purgatives for some time after apparent restoration to health. If the bowels need to be relieved simple enemata are the safest agents, and are usually sufficient. The local measures to be employed comprise leeching, fomentations, and the application of ice; and, if an abscess form, its speedy evacuation. Since those who have once suffered from typhlitis are liable to recurrences, they should, even after apparent cure, take great care in respect of diet, exposure to cold, and other conditions likely to act injuriously.

The due recognition of the fact that so-called 'typhlitis' is, in the great majority of cases, perforative ulceration of the vermiform appendage, determined by the presence of a concretion in its interior, has led to the extensive and, on the whole, highly successful adoption of the surgical procedure of cutting down upon the seat of disease, removing the concretion and such fluid accumulations as may accompany it, and excising, or otherwise dealing with, the diseased part. This may be done not only when an abscess actually presents, but also when the inflammation is still deep seated; and perhaps most satisfactorily, and with greatest certainty of an entirely satisfactory result, when an attack of typhlitis has subsided, with the object, of course, of preventing recurrence.

## B. *Periproctitis*

*Causation and morbid anatomy.*—Inflammation and suppuration about the lower part of the rectum are even more common than the corresponding affections of the cæcum; and their causes are equally various. In many cases this affection is traceable to ulceration (perforative or other) of the mucous membrane; in others it probably originates in the connective tissue which surrounds the rectum. Further, the rectum (again even more frequently than the cæcum) gets involved in inflammation and suppuration originating in the various pelvic and even distant organs. Abscesses, in fact, arising in the abdominal cavity or its walls, or implicating them, are always apt to gravitate into the pelvis, and to commu-

nicate with the rectum. Rectal abscess is frequently connected with the presence of tuberculosis.

*Symptoms and progress.*—Inflammation in the neighbourhood of the lower part of the rectum necessarily produces tumefaction and induration, which may usually be readily detected by digital examination per anum, or by their presence in the perinæum in the immediate vicinity of the anus. In connection with the swelling there are always more or less severe pain and tenderness, which often prevent the patient from sitting down, and are greatly aggravated during the act of defæcation. If suppuration take place, the swelling rapidly increases in size, and the abscess presently opens either into the rectum (usually a little within the internal sphincter) or externally by the side of the anus, or in both of these situations, and discharges exceedingly fetid pus. Simple inflammation around the rectum may subside spontaneously; but an abscess almost invariably results in the formation of a fistula, which is a very obstinate affection, and rarely yields excepting to direct surgical treatment. When an abscess opening into the rectum is connected directly with suppuration of some remote organ, the ultimate prospects of recovery are by no means satisfactory.

The *treatment* consists in the application of fomentations, poultices, or leeches, and the opening of the abscess as soon as the presence of pus is ascertained. The bowels, moreover, should be regulated either by laxatives or by enemata.

## VII. DYSENTERY

*Definition.*—We have already, in describing inflammation and ulceration of the bowels, discussed the various inflammatory processes which take place in the large intestine, and considered the symptoms to which they give rise. These affections, especially if they involve its lower segment, always induce so-called ‘dysenteric’ symptoms, and are usually included in the generic term ‘dysentery.’ But dysentery is also the name of one of the most widespread and fatal of diseases—a disease which, under special circumstances, assumes an endemic or even epidemic character, and is hence not unnaturally regarded as a specific disease, in the same sense as ague and enteric fever are specific diseases.

*Causation.*—Dysentery prevails largely in tropical regions, and more especially in those places which are low and swampy, and surcharged with decaying vegetable matter—in regions indeed which are, for the most part, malarious and breed intermittent fevers. It occurs, however, under conditions and in places which are not productive of ague; it has been in all ages one of the greatest scourges of armies in the field, of beleaguered cities, and of starving populations. According to Sydenham and others of our older writers, it was once a formidable disease in this country; whence in an aggravated and epidemic form it has now almost entirely disappeared. It is probable, however, that enteric fever formed

a large proportion of the cases then termed dysenteric. From its frequent coincidence in area of distribution with ague it is by many regarded as being, equally with that disease, a product of the malarial poison. But the facts that aguish districts are not necessarily also dysenteric; that dysentery, even in an epidemic form, occurs in places and under circumstances which never yield ague; and that ague and dysentery no more graduate into one another than do enteric and typhus fevers, render this view of its origin untenable. The influences of foul water, polluted air, insufficient nourishment, and exposure and over-fatigue in its production are unquestionable, but whether as exciting causes or merely as predisposing causes is by no means clearly established. There is reason, however, to believe that polluted drinking water is an especially active agent in the induction of the disease, but whether by the introduction of a specific poison is, at least, doubtful. We are inclined to regard dysentery as both of non-specific origin and non-infectious; and, on these grounds, introduce its description here.

*Morbid anatomy.*—The morbid anatomy of dysentery has been abundantly described, but the descriptions which have been given of it are various, and do not admit of being readily reconciled. Some of the most trustworthy of recent observers, such as Parkes and Baly, regard it as a disease essentially of the solitary glands of the large intestine, which rise up in the form of hemispherical buttons, varying from the size of a millet-seed downwards, and occasionally attaining the bulk of a split pea. Associated, however, with glandular hypertrophy there is always more or less intense congestion of the general surface of the mucous membrane which becomes sepia-coloured, reddish-brown, or almost black; together with inflammatory infiltration of its substance and of the submucous tissue, which may consequently acquire a collective thickness of one-quarter or even one-third of an inch.

It must, we think, be admitted that dysentery commences with congestion, more or less intense, and infiltration more or less conspicuous of the mucous membrane, in which changes the solitary glands not improbably take a predominant share. This inflammation (at all events in the first instance) usually occurs in scattered patches, which are linear stellate, or irregularly roundish or polygonal, are specially liable to involve the prominent folds, and are sometimes limited to them. The patches may be discrete, or they may run together, forming an irregular network, or they may coalesce completely over a more or less extensive area, and even throughout the whole length of the large intestine. It usually happens that, in addition to the intestinal inflammatory change here adverted to, the affected surface becomes early covered with a thin opaque, granular film, or with such films in patches. These can generally be readily removed from the subjacent surface, bringing with them adherent casts of the Lieberkühnian follicles. They consist, in fact, mainly of an inflammatory overgrowth of the intestinal follicular epithelium.

If the dysenteric attack be slight, the morbid process may cease at the point and convalescence become established without any material inju-

to the bowel. But if it be severe, further changes speedily ensue. These present considerable variety, but consist essentially in the formation of sloughs and (by the separation of these) of ulcers. The sloughs vary in colour, size, shape and arrangement. They may be yellow, like those of enteric fever, or ash-coloured or black. They are sometimes circular and distinct, studding the surface more or less uniformly and thickly; sometimes they occur in irregular groups, and constitute patches of various, and often considerable, extent; sometimes they so run together and are so arranged as to constitute a network, the interstices of which are formed by isolated patches of mucous membrane; sometimes extensive tracts of surface are uniformly and completely destroyed; and in all cases there is a tendency for the morbid process to spread, either by simple ulceration, or by the burrowing of pus beneath the mucous surface, or by sloughing. With the separation of the sloughs ulcers are left, sometimes with ragged, sometimes with abrupt, and often with swollen and congested margins, and with floors formed either by the submucous tissue or by the transverse muscular fibres.

The subsequent progress of the morbid process varies. In some cases more or less perfect cicatrisation ensues; in some, the ulcers assume a chronic character, and remain open, and with little alteration, for an indefinite period; and in either of these cases there is a tendency to the recurrence of active inflammation under slight provocation. When the disease lapses into the chronic form, the affected bowel is apt to remain irritable, to become permanently contracted, and as regards its muscular coat sometimes greatly hypertrophied. It must be added: that perforation of the bowel is an occasional complication of dysentery; that inflammation sometimes pervades the whole thickness of the intestinal walls, extending even to the peritoneal aspect; that more or less hemorrhage from the inflamed or ulcerated surface is almost invariable, while in some cases it is so abundant as to cause death; and that the cicatrisation of dysenteric ulcers not unfrequently causes stricture.

Dysenteric inflammation may occupy any part of the large intestine, or the whole of it, and may be prolonged for a considerable distance up the ileum. It is most common, however, in the lower part of the colon and in the rectum, and is usually most severe and most advanced in these situations.

Other lesions besides those of the bowels are often met with in dysentery. The most common are engorgement of the lymphatic glands in relation with the inflamed mucous membrane, and congestion of internal organs, more especially the liver, spleen, kidneys, and lungs. In association with the dysentery of tropical climates abscess of the liver is not uncommon. This complication is referred by Dr. G. Budd to portal pyæmia, taking its rise from the diseased mucous membrane of the bowel. Hepatic abscess, however, sometimes originates simultaneously with the dysentery, sometimes precedes it; and hence it seems more probable that the two lesions are concurrent effects of the same cause, and not dependent the one on the other.

*Symptoms and progress.*—The symptoms of dysentery comprise those of pyrexia and those due directly to the morbid processes going on in the large intestine—the latter being mainly determined by the excessive irritability and tendency to spasmodic contraction of the larger bowel, and by the fact of the constant discharge into it of the morbid products of the diseased mucous surface.

In the milder forms of the disease, the patient, after suffering, perhaps, for a short time from heat and dryness of skin, clamminess of mouth, and vague griping pains, is attacked almost suddenly with an uncontrollable impulse to evacuate his bowels, and probably passes a solid motion with unusual ease—the mass being invested in a greater or less abundance of greyish or colourless mucus. The usual sense of relief, however, does not follow, and he probably finds himself compelled to sit straining at stool, with fits of spasmodic violence, during which he discharges small quantities of offensive mucus, and probably a minute faecal lump or two. With the continuance of the affection the febrile disturbance continues; the tongue probably becomes coated; a constant sense of uneasiness, heat, or burning pervades the anus and adjoining parts of the rectum, and perhaps the rest of the large intestine. The patient suffers from frequent tormina, and impulse to evacuate the bowels—the efforts being attended with much tenesmus, and the discharge mainly of small quantities of mucus. This may be stained with faecal matter, and is often intimately mixed with blood, and may consequently present very much the appearance of pneumonic expectoration. But, notwithstanding the almost constant efforts at defaecation, there is, so far as actual faecal matter is concerned, almost complete constipation. A few scybala only are passed from time to time. Cases of this kind may subside in the course of a day or two, and seldom last longer than a week or ten days. Nevertheless some irritability of the bowels, uneasiness after defaecation, and tendency to constipation, may trouble the patient for a considerable time after he seems to have regained in other respects his ordinary good health.

In the more severe forms of dysentery the symptoms are similar in kind, but much more intense. The disease is usually ushered in with high fever, often with alternate chills and flushes of heat, sometimes with distinct rigors, and occasionally even with convulsions. The skin is hot, the pulse accelerated; there are febrile pains and headache, anorexia, thirst, and dryness and furring of the tongue. In this, as in the former case, the intestinal affection is usually first indicated by the occurrence of griping pains, which are presently followed by the evacuation of the contents, often solid, of the lower bowel. But soon the griping becomes frequent and severe, calls to stool are incessant, and the patient suffers from almost constant tenesmus. The matters discharged from the bowels are at first a whitish, brownish, or olive-coloured glairy or jelly-like mucus; but this soon gets sanguinolent, and not unfrequently intermingled with considerable quantities of dark and maybe clotted blood. After a while the discharges commonly assume those characters which give them a resemblance to 'meat-washings': they become thin, watery, turbid, reddish, and dirty-

looking, and contain brownish or blackish particles, which are fragments either of altered blood-clots or of sloughy mucous membrane. It is at this time also that the patient frequently passes soft membranous pellicles, which are either tracts of mucous membrane detached in bulk, or portions of false membrane. Dysenteric evacuations are further characterised : by a peculiar and almost insupportable fetor, which increases in intensity with the supervention of sloughing ; by containing a large quantity of dissolved albumen ; and by the occasional presence of small solid faecal lumps or scybala. They sometimes become purulent. The frequency with which the bowels act is often very remarkable. In some cases the patient seems for a length of time never to cease discharging small quantities of fluid. The bowels are often relieved four or five times in the hour, and sometimes as many as ten or twenty times in the same period. The quantity of fluid passed, however, is not necessarily in relation with the frequency with which the bowels act. In many cases, especially at the beginning, the discharge is scanty ; but later on considerable quantities of serous fluid, or blood, or both, are apt to escape, and the total bulk of these discharges in the twenty-four hours is hence often very large.

Associated with tenesmus and alvine flux are burning pain within the anal orifice, and a constant sense of the lodgment there of something which needs to be got rid of ; there is also more or less burning pain and tenderness on pressure in the course of the large intestine and especially of those parts which are chiefly involved. At first probably the abdominal parietes are rigid and retracted ; but before long flatus accumulates and the abdomen consequently gets enlarged and tympanitic ; the tongue becomes thickly coated ; the patient complains of thirst, loathes food, and not unfrequently suffers from nausea and vomiting ; the urine is scanty and high-coloured, and its discharge sometimes attended with pain or difficulty ; the febrile excitement which ushered in the disease gets replaced by profound depression ; the skin may yet be hot and dry, but the pulse becomes small, feeble, and rapid, the face anxious, and the patient restless, sleepless, and desponding.

Cases which end favourably usually manifest signs of amendment from the sixth to the tenth day ; these consist in abatement of fever and other general symptoms, and gradual cessation of tenesmus and the peculiar dysenteric stools. But convalescence is usually much protracted ; and some time elapses before the bowels completely regain their normal tone. In cases which end fatally the pulse increases in rapidity, loses fulness and power, and often becomes scarcely perceptible ; the surface tends to grow cool ; the face and extremities acquire a shrunk and dusky aspect ; the tongue becomes dry and brown or black ; hiccough and vomiting come on ; and the abdomen grows more and more tympanitic. Although probably continuing restless and desponding, the patient often retains his senses perfect to the last ; sometimes, however, he becomes delirious (in some cases, indeed, delirium comes on early), and he may then pass into a state of stupor or coma. It very commonly happens that, with the

increase of tympanites, the abdominal pain, colic and tenesmus all subside and even disappear wholly. The symptoms which precede death, and the mode of death, are necessarily modified to some extent by the special circumstances of the case; they are, for example, somewhat different in such cases as are attended with profuse hemorrhage from what they are in those in which intestinal perforation takes place, or which are complicated by hepatic abscess, or where the patient sinks under the influence of the uncomplicated disease. Under all circumstances, however, the immediate cause of death is asthenia.

Many cases of acute dysentery, instead of taking either of the two courses which have been considered, become chronic; and the disease continues, with occasional remissions and exacerbations, for an indefinite period. The patient is then an almost constant sufferer from colic and tenesmus, and the discharge of offensive liquid stools, containing little true fecal matter, and from retention, often to a very uncomfortable extent, of his solid feces; he complains of abdominal tenderness and uneasiness; his tongue is in some cases dry, glazed, and fissured, in others coated, in others almost normal; and his appetite presents equal variations; more or less sickness is often present; and he becomes emaciated, weak, anæmic, anasarctous, and often hectic. If an hepatic abscess be present, the symptoms, or many of them, are aggravated, and probably the indications of hepatic tumour are presently superadded. Chronic dysentery varies greatly in its severity, and in some cases, even though lasting for years or throughout life, is, excepting from the discomfort which attends it, of comparatively little importance.

As a rule, sporadic dysentery is not a very fatal disorder; but the epidemic form is usually attended with a high mortality; and although, even here, the ratio of deaths to attacks is sometimes small, the cases are so numerous, and the total mortality usually so high that it is justly regarded as one of the most fatal of epidemic diseases.

*Treatment.*—There is little unanimity of opinion with regard to the treatment of dysentery: some authors strongly advocate the copious abstraction of blood, if not by venesection, at any rate by leeches; some place their chief reliance on calomel in large doses; some regard ipecacuanha as almost a specific; some pin their faith to purgatives, some to opiates; while, on the other hand, each of these remedies has been condemned. Of the immediate relief which follows the abstraction of blood there is probably little doubt; but it is obvious that the marked tendency to asthenia which exists in dysentery supplies a powerful argument against the indiscriminate and excessive use of blood-letting. As a rule, it is doubtless unnecessary; but if employed it should be employed early, and preferably effected by the application of leeches to the tender regions of the abdomen. Calomel has been administered (as it was formerly in cholera) in large doses with reputed success; it has, however, fallen into disuse, and probably deservedly. Ipecacuanha has enjoyed a long but various reputation. It was formerly regarded as an almost unfailing specific, and at the present day is very highly esteemed. There are at least two

antagonistic principles on which it is administered. By Trousseau and other French authorities it is given in doses of ten or twelve grains of the powder every ten minutes or so, until copious vomiting results—the essence of the treatment being, according to them, the production of a powerful evacuating effect upon the stomach; by English army surgeons, on the other hand, it is recommended to be given in a large dose (twenty-five to thirty grains), which is to be repeated at the end of eight or ten hours; but to be given, either guarded by opium, or with other precautions against sickness, in order that the remedy may act directly, or indirectly through the system, on the affected mucous surface. Bretonneau advocates the use of saline purgatives in large doses, and in this advocacy he is strongly supported by Trousseau. Opium and astringents are often employed; but the former (except in infinitesimal doses) is strongly condemned by the last author.

It may, we think, be fairly asked whether there are any good grounds for believing that dysentery is more amenable to treatment, specific or non-specific, than other forms of enteritis are; and whether there is sufficient reason for adopting a radically different treatment from that which has been found generally useful in enteritis? In acute and severe cases we should be disposed in the first instance: to apply hot fomentations to the belly, and, if there be much local pain and distress, to abstract blood by means of ten, twenty, or thirty leeches; to exhibit opium, or opium with ipecacuanha, in doses sufficiently large or sufficiently frequently repeated to relieve the tormina, tenesmus, and abdominal pain; and to use enemata either simply to wash out and cleanse the lower bowel, or to soothe it, or for the purpose of applying astringents or other medicaments directly to its surface. We should prefer, in the early stage of the disease, small enemata of gruel containing laudanum, or opium or morphia suppositories. The patient's diet should consist of milk, gruel, broths, eggs, and such-like articles, together with such a proportion of alcoholic stimulants as the case may seem to need. If sickness be present, it must be treated with ice, and such remedies as are generally useful in relieving sickness. When the dysentery passes into the chronic state, the use of astringent medicines and of vegetable tonics is indicated. The former may comprise copper, lead, iron, and tannin, together with other vegetable astringents, the latter a wide range of vegetable infusions. At this period also enemata are likely to be serviceable; of which those containing copper, lead, tannin, sulphate of zinc, or nitrate of silver have been strongly recommended, in the belief that they have a direct beneficial action on the diseased mucous membrane. We believe it to be a good plan to wash out the bowel night and morning with as large an injection of warm water or gruel as can be introduced without pain, and then to insert a morphia suppository. In treating dysentery it must not be forgotten that in both acute and chronic cases faecal matter tends to accumulate above the diseased portion of bowel, and that this needs from time to time to be removed. For this purpose it may be necessary to administer an occasional purgative. In mild cases of the disease it is

often well to commence the treatment with a dose of castor oil, and to continue it with mild astringents, such as compound kino powder, Dover's powder, or aromatic chalk and opium.

---

### VIII. PERITONITIS

*Causation.*—Peritoneal inflammation is common in both sexes and at all periods of life. It is due to various causes. In some cases it is idiopathic, or the result of exposure to cold and wet, or generally to those exterior conditions to which inflammations of other organs are so commonly traceable. Idiopathic peritonitis may attack the robust and healthy; it is more common, however, in those who are anæmic, debilitated, or broken down in constitution, and in those who suffer from obstructive diseases of the heart, lungs, or liver, and especially in such as are labouring under chronic Bright's disease. In many cases peritonitis is due to the simple extension of inflammation from neighbouring parts. It is thus developed, in the course of enteritis or gastritis, in connection with inflammatory affections of the liver, spleen, kidneys, or bladder, and in dependence on pleurisy, pericarditis, or inflammation of the abdominal parietes. The most fruitful causes, however, of grave peritoneal inflammation by simple extension are inflammation of the ovaries, uterus, and other pelvic organs in females, and especially that form of uterine inflammation which follows upon parturition. In many cases, again, peritonitis is caused by mechanical injury: sometimes by external wounds; more frequently by the perforation or rupture of some viscus, and the extravasation of its contents or of foreign matters into the peritoneal cavity. Among such cases may be enumerated: ulcerative perforation of the stomach and duodenum; perforation of the small intestine (usually the ileum) by tubercular, typhoid, or other ulcers; perforation of the cæcum, vermiform appendage, colon, or rectum, consecutive to tubercular or typhoid ulcers, dysentery, or mere over-distension; rupture of an hepatic abscess, of the gall-bladder or common bile-duct, of an hydatid cyst, or of a psoas, renal, or other abscess; rupture of the uterus or ovarian cysts; and, besides these, the laceration, from external violence, of the liver, spleen, kidneys, intestine, or bladder. Further, peritonitis is a frequent concomitant of abdominal tubercle or carcinoma, and a not uncommon result of pyæmic or metastatic processes.

*Morbid anatomy.*—The morbid changes which take place in the inflamed peritoneum are precisely similar to those attending inflammation of other serous membranes. They consist in dilatation of the minute vessels, with accumulation of blood within them, and infiltration and thickening of the subserous tissue; and in inflammatory hyperplasia of the epithelial investment, with effusion from the subjacent vessels of modified plasma of the blood, of which part coagulates on the surface, forming, with entangled corpuscles, a false membrane, and part (mainly

fluid) accumulates in the cavity. The first visible indications of peritoneal inflammation consist, in most cases, in more or less intense capillary congestion, which is usually observed to extend in bands (determined by the pressure of the organs against one another) along the intestines; and in loss of polish, due to commencement of inflammatory exudation. With the advance of the disease, the congestion becomes more intense, and patchy, and sometimes complicated with subserous extravasations; and the solid inflammatory exudation increases in quantity. This forms in the first instance a thin, greyish, granular lamina; but as it increases in thickness it acquires a more distinctly yellow tinge, and becomes, according to its quantity and position, ribbed, villous, papular, or honeycombed. The false membrane varies in thickness from a delicate film to a quarter or half an inch or more; and in quality from a mere pulp to a coherent elastic lamina. It usually acquires toughness with age; and the deeper seated portions are always tougher than the more superficial. It tends to accumulate in the dependent parts of the peritoneal cavity, and to cause adhesion between neighbouring organs. The fluid effused in the course of peritonitis is often small in quantity, and, subsiding into the pelvis and lumbar regions, apt to escape detection; on the other hand, it is sometimes very copious, and causes much abdominal distension. It is chiefly abundant in chronic cases. It is usually opalescent, containing exudation-corpuscles, and fibrinogen, which readily coagulates. The spaces occupied by the fluid are commonly traversed by filaments, bands or bridles, of coagulated lymph.

Peritonitis, even when of local origin, generally soon involves the whole of the peritoneal surface. In some cases, however, it remains localised. Thus it may be confined to the neighbourhood of the liver, spleen, cæcum, or pelvic organs. The great omentum not unfrequently effectually limits its spread. Convalescence from simple peritonitis is attended with absorption of the dropsical effusion, subsidence of the inflammatory congestion, and organisation of the false membrane, with its gradual conversion into connective tissue. The usual consequences are that the peritoneal surface gets thick and opaque, and the viscera united to neighbouring parts and compressed by the contracting adventitious membrane. Thus the liver and spleen become adherent to the diaphragm; and the small intestines grow together, and are not unfrequently welded into an apparently homogeneous lump. Further, the liver and spleen, and other organs in a less degree, are apt to get studded with opaque fibroid patches which may attain a thickness of  $\frac{1}{4}$  inch or more, and present an almost cartilaginous consistence and aspect.

In many cases peritonitis becomes suppurative. Sometimes, as in the puerperal variety, the inflammation presents this character universally and from the beginning; the effused lymph is more abundant, opaque, yellow, and pulpy than in non-suppurative cases, and obvious pus is poured out into the peritoneal cavity. Where inflammation results from the perforation of some viscus or sac and the escape of irritating matters, general peritonitis of the ordinary adhesive character is often at once excited, and

thus the effused matters become confined to some limited district. In such cases a circumscribed abscess frequently follows, which may possibly undergo cure by the discharge of its contents either externally or into the bowel. But in some cases groups of such abscesses form; and sinuses extend in various directions—either among the peritoneal adhesions, or in the substance of the mesentery, meso-colon, great omentum, and other such parts; and fistulous openings may be established in various situations. General suppurative peritonitis may of course result from the escape of fecal or other irritant matters into the peritoneum, especially if the escape be sudden and profuse; in which case, if the accident be not immediately fatal, the false membrane becomes exceedingly thick and tough, and the general surface acquires the usual characters of that of a chronic abscess.

Occasionally in peritonitis, as in other serous inflammations, copious hemorrhage from the newly formed vessels of the adhesions takes place into the serous cavity.

In connection with this subject we may draw attention to the fact of the not unfrequent formation, independently of general peritonitis, of circumscribed abscesses in the abdominal cavity, the causes of which are sometimes obvious, sometimes obscure and undiscoverable. These may occur in any situation; but they affect some localities more than others, and especially the neighbourhood of the stomach, the iliac regions, and the cavity of the pelvis. In the first of these situations they may lie between the stomach and the liver or diaphragm, or between the cardiac end of the stomach and the parietes, simulating splenic disease, or between the stomach and the transverse colon, or may occupy the cavity of the lesser omentum; and they may open either through the outer abdominal walls, or into the stomach or colon, or through the diaphragm into the pleura or lung, or in two or more of these directions at the same time. When occurring in the iliac regions they may either open externally or take any of the courses which perityphlitic abscesses are apt to take. If they occupy the pelvis they tend to open into the rectum or bladder, and in the female into the vagina.

*Symptoms and progress.*—The symptoms of peritonitis are mainly those of fever in combination with acute abdominal pain, increased by pressure. They are liable, however, to considerable variety; and many others of more or less importance are usually superadded. The phenomena of peritonitis differ greatly, indeed, in relation to the extent and intensity of the inflammation and to the circumstances under which it arises.

Acute idiopathic peritonitis, although by far the least frequent variety, yet displays the symptoms and course of the disease in their simplest and most typical form. Its mode of onset varies. Sometimes the outbreak of the local affection is preceded by a few days of vague sense of illness; sometimes it is marked by the occurrence of febrile symptoms, and even of rigors; sometimes the first indication of disease is sudden vomiting or purging, or both, or gradually increasing dysuria, or in females the

occurrence of menorrhagia. But, whatever the initiatory symptoms, the patient before long complains of febrile disturbance, and of burning, aching, pinching or cutting pain, probably limited to some region of the abdomen, and increased by pressure or movement. The pain is usually in the first instance across the lower part of the abdomen; and, if the patient have not yet taken to his bed, he sits, moves, and walks with his body bent in a stooping posture. Soon, however, the signs of peritoneal inflammation extend and increase in severity; and at the same time the patient's general symptoms assume a more serious aspect. The abdominal pain becomes exceedingly severe, and is aggravated beyond endurance by the slightest movement. He takes to his bed, where he lies motionless on his back, with his head and shoulders elevated, and his thighs and legs flexed so as to diminish as far as possible the pressure of the abdominal walls on the internal organs; and breathing by means of the intercostal muscles only, and shallowly, with the same object. He not only shrinks from the pressure of the hand, but generally cannot bear even the weight of the bed-clothes, or of the poultices or fomentations which may have been ordered for his relief. The pain often is comparatively trivial so long as perfect rest is maintained; but it breaks out afresh whenever a cough, sneeze, hiccough, or deep inspiration takes place, and is liable to periodical and in many cases frequent aggravations, due to the peristaltic movements of the bowels. In association with these phenomena there is generally distinct fever. The temperature may reach  $104^{\circ}$  or  $105^{\circ}$ , but is very often not above  $100^{\circ}$  or  $101^{\circ}$ . The skin is hot and dry; the face flushed; the pulse increased in frequency and sharpness; the respirations augmented to 30 or 40 in the minute; and the tongue coated and clammy, if not dry. Vomiting is often present, but is no necessary feature of the disease; and thirst is usually complained of. The bowels are generally constipated, but are not unfrequently loose. The urine is scanty, high-coloured, and sometimes retained; or there may be irritability of the bladder with painful micturition. The presence of marked intercostal respiration indicates involvement of the upper part of the abdominal cavity; interference with micturition points to implication of the pelvic peritoneum. Further, there is reason to believe that the occurrence of vomiting or diarrhoea is referrible in some cases to inflammation of the serous surface of the stomach or bowels. If the disease take a favourable turn, which indeed at the end of a few days it usually does, the severer symptoms gradually remit: abdominal pain and tenderness subside, vomiting ceases, the respirations become natural, and the temperature and pulse return to their normal condition. If, on the other hand, the case be about to prove fatal, important changes in the symptoms supervene; the abdomen becomes distended, partly from effusion of fluid, mainly, however, from accumulation of gas in the intestines; pain and tenderness, though sometimes continuing and even becoming aggravated, very frequently undergo great diminution and sometimes cease entirely; sickness probably increases, and hiccough supervenes; the temperature falls, the extremities get cool or cold, the face pale or livid and

pinched and anxious in expression, and the skin suffused with cold sweats ; the pulse increases in frequency, rising, it may be, to 130, 140, or 160 in the minute, and gets small, thready, and weak ; the respirations quicken, reaching, perhaps, 40 or even 60 in the minute ; and the tongue becomes more thickly coated, and this and the lips dry. The patient, in fact, for the most part retaining his consciousness, falls rapidly into a state of profound collapse, in which he presently dies. Sometimes delirium comes on before the fatal event, and death may then be preceded by coma.

The tendency to failure of circulation and to collapse is one of the most remarkable characteristics of peritonitis, as it is of enteritis. And it is important to bear this fact in mind ; for even in the early stage of the disease, when the pulse is little accelerated, and sharp, perhaps strong, and the patient appears to be suffering from what is termed ' the sthenic form ' of peritonitis, a little over-exertion, some unwonted effort, may readily induce dangerous collapse.

It may be added that, while the presence of dropsical effusion adds to the distension of the abdomen, it does not, as a rule, materially aggravate the danger of the case ; and that, if sufficiently abundant, it may be detected either by its causing dulness and bulging in the flanks, or by the presence of fluctuation ; and further, that peritoneal inflammation constantly causes basic pleuritis, which may possibly be recognised during life ; and that peritoneal friction may also occasionally be detected either by the fremitus it occasions or by auscultation. When fluid and lymph are together present, a very coarse kind of fremitus or crepitation can often be elicited by pressure, especially in the scrobiculus cordis or its neighbourhood. Death may occur as early as the second or third day of the attack, or may be delayed to the end of a week or ten days. When, however, the disease is prolonged beyond this date, it usually lapses into the chronic condition ; in which, either inflammation of little intensity is kept up by the development of tubercles or some other cause, or the chronic symptoms are due to the formation of a circumscribed abscess.

Puerperal peritonitis differs from the idiopathic affection chiefly in the circumstances under which it arises, in its usually rapidly fatal course, and in the fact that it is often associated with, if not dependent upon, pyæmia taking its origin in inflammation of the uterine mucous membrane. It generally begins within a few hours or a few days after parturition, with severe rigors, attended with high elevation of temperature, and soon followed by intense pain across the lower part of the belly, and suppression or modification of the lochial discharge. The main points in its symptomatology, by which it differs from the simple form of the disease, are the speedy supervention of collapse, and the more general and early implication of the sensorial functions. Further, the symptoms are, in many cases, compounded of those of the local affection and those of pyæmia.

Peritonitis from perforation is one of the most common and interesting forms of the disease, and by far the most fatal of them. When perforation takes place in a person who appears to have been, up to the very

moment of the accident, in the enjoyment of good health—as sometimes happens in cases of perforating ulcer of the stomach, rupture of the urinary bladder, or perforation of the ileum in mild enteric fever, the symptoms usually are : sudden and intense pain in the region of the lacerated organ, speedily followed by all the local indications of violent peritoneal inflammation ; and extreme and immediate collapse, shown by pallor and coldness of surface, cold sweats, scarcely perceptible pulse, fainting, and vomiting. In some cases the patient dies of this primary collapse in the course of a few hours ; and there may be little in the history or symptoms of such a case to distinguish it from one of Asiatic cholera, fatal before the supervention of diarrhœa ; or from one of sudden effusion of blood into the stomach and bowels, fatal without hæmatemesis or melæna ; or from one of ruptured heart or internal aneurysm. But more frequently the patient rallies somewhat, and the collective symptoms of inflammation, fever, and peritoneal mischief become more clearly developed. Collapse, however, generally soon reappears, and the patient usually sinks after a period varying between twelve hours and two or three days. But the symptoms of perforative peritonitis are not always so intense and striking. Indeed, they are often exceedingly difficult of recognition, and vague, when they occur in the course of abdominal diseases, whose proper symptoms tend to mask them ; for example, dysentery, enteritis, and those rare cases in which peritoneal suppuration causes perforation of the bowel from its serous aspect. By far the most common cases of masked perforative peritonitis are those which occur in the second or third week of severe enteric fever, when the patient is prostrate with diarrhœa, and is dull, confused, and delirious, and to a large extent insensible to painful and other impressions. The evidences of perforation are then to be sought, not so much in obvious sudden collapse or intensity of abdominal pain, as in the general indications of failing strength—namely, increased weakness and rapidity of pulse, coldness of extremities, lividity of face, and diminution of intelligence, and of power over the limbs and sphincters ; and in the supervention or increase of tympanites, with general abdominal tenderness, as shown by the expression and actions of the patient when pressure is made upon the surface of the abdomen. But although peritonitis from perforation is a well-nigh hopeless affection, there is reason to believe that it is not entirely hopeless. We have known of a case in which the patient certainly survived the accident for a fortnight ; and several cases have been put on record in which there are good grounds for believing that a cure was effected after the formation of an abscess and its discharge by the bowel or some other route.

Peritonitis is not always the serious disease which has been above described. In a large number of cases it is, even if general, slight ; and in a large number of cases, also, it is of local origin, and continues localised. The symptoms of partial peritonitis are the same in kind as those of the more general and more severe affection ; but the local indications are limited to some comparatively small area, and the general symptoms, if there be no serious complications, are comparatively slight.

It must not be forgotten that the adhesions which peritonitis leaves behind are not unfrequently a source of discomfort or danger. In some cases the compression of the bowels which they induce keeps up a tendency to colicky pains and intestinal disturbance; in some cases slowly contracting adhesions gradually compress a length of bowel and render it practically impervious; while in other cases, again, bridles or bands are formed, behind which coils of bowel are apt to slip and get incarcerated or strangulated.

Peritonitis is liable to be confounded both with enteritis and with colic; but is generally distinguishable from enteritis by the absence of intestinal obstruction, and from simple colic by the fact that the latter is unattended with fever, and that its pain is usually relieved in some degree by pressure.

The symptoms of abdominal abscesses, whether they be associated with peritonitis or not, are often very obscure. More or less feverishness and constitutional disturbance are usually present, and also, as a general rule, special symptoms dependent on their seat and the organs with which they are in relation. Their main local indication is the presence of a tumour which is more or less tender and painful, and in which fluctuation may generally be more or less distinctly felt. Sometimes, owing to the thickness and density of their walls, they are hard and unyielding, and simulate solid tumours. They tend, of course, to enlarge and to point, and if they do not open externally sometimes rapidly disappear by bursting into the peritoneum or some hollow viscus. Under such circumstances either acute peritonitis is suddenly excited, or pus may suddenly be vomited, or discharged by expectoration, or escape by the bowel, bladder, or vagina: and communications may be established between neighbouring organs leading in some cases to the vomiting of solid fæces, in some to the discharge of fæcal matter from the urethra or vagina, in some to the escape of undigested food by the rectum. Such abscesses are often very chronic in their progress, and often lead ultimately to a fatal result. It may be difficult, at any rate for a time, to distinguish them from malignant growths; and indeed abscesses not unfrequently arise in connection with such growths.

*Treatment.*—The principles of treatment in peritonitis are sufficiently simple: they are, the maintenance of perfect rest, the administration of opium, and the application of leeches and other remedial agents to the surface of the abdomen. The patient should be placed and propped up in that position which he finds easiest, usually upon his back, with his knees and shoulders elevated. His abdomen should be defended from the weight of bed-clothes by means of a suitable cradle. Opium or morphia should be given sufficiently frequently, and in sufficiently large doses, to assuage the patient's pain and keep it in abeyance, to quiet the action of the bowels, and to promote comfort and sleep; it may be given by the mouth, or by subcutaneous injection. If the case be severe and in an early stage, from ten to thirty or forty leeches should be applied to the surface of the abdomen; and bleeding should be promoted by fomentations or light poultices.

Subsequently hot fomentations, turpentine epithems, mustard plasters, or blisters may prove serviceable. On the other hand, cold applications (evaporating lotions, cold compresses, and ice-bags) have been largely advocated, and in many cases have proved of great advantage. It is important, moreover, in many cases, to relieve accidental complications, such as nausea and vomiting, dysuria and the like. To meet the former indications, recourse must be had to ordinary anti-emetic measures; to meet the last, the catheter may need to be employed. It is of course essential to maintain, so far as we possibly can, the patient's bodily strength; for which purpose nourishing diet, mainly in the fluid form, must be frequently administered in small quantities, and alcoholic stimulants, in amounts depending on the condition of the patient, combined therewith. If he cannot retain food on the stomach, it must be given by the rectum. It need scarcely be said that cases of peritonitis passing rapidly into collapse, and especially therefore cases of puerperal peritonitis, bear depletory measures less well than others; and that hence such treatment is admissible only in quite their early stage. These cases, moreover, demand, more than others, early and considerable stimulation; and ammonia and ether, or similar agents, may be employed in addition to alcohol. When peritonitis is caused by perforation, our main reliance may be placed upon opium; and here especially it is of vast importance that the movements of the bowels be restrained, that purgatives be religiously avoided, and that the stomach be not overloaded with nutriment. If the patient survive for two or three days, some hope (remote, no doubt) may be entertained of his final recovery. But, in order to promote this consummation, it is always desirable to investigate carefully from day to day the condition of the abdomen, in order to detect the presence of any circumscribed abscess there, and as soon as may be to evacuate its contents. In severe cases of sudden onset, especially if there be any reason to suspect perforation of some viscus or the presence of irritating matter in the peritoneal cavity, abdominal section may properly be performed with the object both of seeking for and dealing with the source of peritonitis and of washing out the contents of the cavity—such operations, however, should be performed early.

---

## IX. CIRRHOSIS OF THE STOMACH AND BOWELS

*Morbid anatomy.*—Fibroid infiltration or thickening (a condition also termed 'cirrhosis,' and having a close anatomical relation with cirrhosis of the liver) occasionally takes place in the walls of the stomach and intestines. Thickening, which differs little, if at all, from this, is usually present in the neighbourhood of chronic ulcers of the stomach. When occurring independently, all the coats of the stomach as a rule are implicated, but more especially the muscular coat and the submucous tissue—the mucous surface being thrown into prominent folds over the affected area. The whole stomach is sometimes thus diseased, and is then usually

diminished in size, tough, and retaining its form like an india-rubber bottle. But commonly the affection is limited to the neighbourhood of the pylorus, which then becomes constricted, and leads to general dilatation of the organ. The gastric walls, especially at the pyloric end, sometimes attain a thickness of half an inch or an inch, and present to the naked eye most of the usual characters of scirrhus. The morbid growth, however, differs from scirrhus in consisting wholly of fibroid tissue, and not possessing malignant properties. The intestines are much less frequently affected than the stomach.

The *symptoms* referrible to cirrhosis are vague. They resemble, for the most part, those of the early stages of carcinoma. When the pylorus is obstructed, the symptoms of that condition necessarily manifest themselves; when the large intestine is involved, the phenomena of stricture presently supervene.

---

### X. TUBERCLE (*Abdominal Phthisis*)

*Morbid anatomy.*—Tubercular disease of the mucous membrane of the stomach is so rare, and so little is known about it clinically or otherwise, that it is needless to do more than record the fact of its occasional occurrence.

1. *Bowels.*—The mucous membrane of the bowels, on the other hand, is one of its most frequent seats; and, indeed, intestinal ulceration is, in a very large proportion of cases, of tubercular origin. Tubercle of the bowels occurs in rather more than one-half of the total number of cases of pulmonary phthisis, and rarely, if ever, independently of it; it is frequently associated, also, with tuberculosis of the peritoneum and other abdominal organs. It affects primarily Peyer's patches and the solitary glands; and in the small intestine, therefore, is always most abundant and most advanced immediately above the ileo-cæcal valve, from whence upwards, even though it extend throughout the whole ileum and jejunum, it gradually diminishes. It attacks the cæcum more frequently than any other part of the large intestine, involving also the ileo-cæcal valve and vermiform appendage; but it may form patches throughout the whole length of the colon. The large and small intestines are affected with equal frequency, and conjointly about twice as often as each suffers separately. The tubercles appear as grey granules, or yellow cheesy masses, in the substance of the glands, and generally soon undergo softening, producing small, deepish ulcers with thickened, overhanging edges. When several tubercles have softened side by side, as occurs in Peyer's patches, the ulcerated area presents in the first instance a kind of honeycombed appearance—the small ulcers being separated from one another by bridles of thickened mucous membrane; and the general margin, which is also thickened, presents a sinuous or scalloped outline. Tubercular ulcers gradually tend to spread by the successive formation and softening of tubercles at their edges; and thus often creep over a

considerable area. The whole mucous lining of the cæcum is sometimes destroyed in this manner; and extensive tracts of ulceration often stud the surface of the colon at more or less distant intervals. In the small intestine tubercular ulcers have a remarkable tendency to spread transversely, and frequently form bands, from half an inch to an inch or more wide, occupying its whole circumference. In most cases the ulcerative process progresses up to the patient's death, and occasionally leads to serious hemorrhage or to perforation. Sometimes the ulcers cicatrise more or less perfectly—some, indeed, cicatrising while others are spreading or new ones forming. Tubercular cicatrization leads to considerable contraction of the bowel and even to the production of stricture. Sometimes tubercles dry up or get absorbed without undergoing ulceration, leaving behind them pigmented cicatrix-like patches which have some resemblance to the scars left in the skin by superficial lupus. Extensive ulceration of the large intestine, presenting all the characters of chronic dysenteric ulceration, is often met with in cases of chronic phthisis, where there is no discoverable tubercle in any part of the bowels except the ileum, and where, therefore, it may be a question as to whether the ulceration is of tubercular origin, or has arisen in mere non-specific excoriation such as might be caused by the constant passage of irritating secretions from the tubercular bowel above.

2. *The peritoneum and abdominal lymphatic glands* are often affected. Generally in cases of tubercular ulceration of the bowel, and certainly in all cases of extensive ulceration, grey granulations stud the serous surfaces corresponding to the diseased area. But such formations are for the most part purely local, and of little importance. There are other cases, however, less common, yet not unfrequent, in which the tendency to the growth of tubercles is general throughout the serous membrane, and in which ulceration of the bowel is not only not their starting point, but often altogether absent. Peritoneal tuberculosis is almost always associated with similar disease of other parts; most commonly with pulmonary phthisis, but not unfrequently with tubercular affection of the bowels and other abdominal viscera. It complicates a very large proportion of those cases in which the pleura, spleen, liver, kidneys, uterus and Fallopian tubes, or brain is involved; and not unfrequently seems to be due to extension of disease from the pelvic organs. Peritoneal tubercles are sometimes miliary and grey, and from the size of a poppy-seed downwards. Sometimes they form lobulated masses from the bulk of a tare up to that of a hazelnut: presenting for the most part an opaque buff-colour, often mottled with black points or patches; and exhibiting a cheesy aspect and consistence, which are modified by the greater or less abundance of fibroid material which invests and permeates them. Sometimes, again, but much more rarely, there are found, lying between organs which are adherent, tubercular laminæ of considerable thickness and extent. Peritoneal tubercles, indeed, rarely exist independently of the effusion of lymph and the presence of false membranes. The large tubercular masses are usually comparatively few in number; the miliary tubercles, on the other hand, are,

as a rule, thickly set and innumerable. In the latter case the peritoneal surface is often found covered with a layer of greyish, transparent, adherent, and toughish lymph, which not only invests the abdominal organs, but unites them more or less with one another, and in the substance of which tubercles are disseminated as opaque grains; and the great omentum is often much thickened from infiltration with similarly combined inflammatory products and miliary tubercles.

In association with the presence of tubercles all the usual phenomena and sequæ of simple inflammation, such as streaky redness, fibrinous effusion, and dropsical accumulation, are apt to manifest themselves, sometimes, also, suppuration, sometimes profuse hemorrhage. Further, it occasionally happens that, during the progress of peritoneal tuberculosis involving the intestinal walls, perforation of the latter takes place. The most important of these phenomena from its frequency is undoubtedly ascitic effusion.

The abdominal lymphatic glands are a frequent seat of tubercle; mainly, however, the glands of the mesentery, and more especially those of them which are in relation with tuberculous intestine. Tubercle of these organs is mostly secondary to tubercle either of the intestines or of the peritoneum. It appears in them, and for the most part in their peripheral portions, in the form of minute, hard, grey points, which occur in groups and tend gradually to run together, and to form imbedded masses which soon undergo caseous change. Glands thus affected may suppurate and even rupture into the peritoneal cavity; or they may get slowly converted into mortary or calcareous lumps. Tubercular glands are usually enlarged; sometimes, indeed, attain the size of a pigeon's egg. When, however, they undergo calcareous change they contract and acquire an indurated capsule. Tubercular mesenteric glands sometimes, especially in children, collectively form masses easily detectable through the abdominal walls; but there is little doubt that most of those cases of extreme enlargement of these glands which were formerly regarded as tubercular were really cases of lymphadenoma or some other form of malignant disease.

*Symptoms and progress.*—1. *Bowels.*—The symptoms of tubercular ulceration of the mucous membrane are in no degree specific; and they vary according to the part of bowel affected. When the disease is limited to the ileum there is probably pain and tenderness in the region of the cæcum, with frequent griping. The bowels may be confined or loose, but are more often, perhaps, irregular. When the large intestine is involved, the symptoms closely resemble those of chronic dysentery, and, indeed, are by no means necessarily distinguishable from them. The points of chief clinical importance in reference to intestinal tuberculosis are: first, that the disease is for the most part a progressive one, and that hence diarrhœa having once declared itself tends to become progressively more and more severe and intractable; second, that during its progress the patient rapidly undergoes extreme emaciation, becomes excessively feeble, and suffers in an aggravated form from night sweats, imperfect circulation (indicated by blueness of nose and coldness of extremities), and the other phenomena

which attend rapid impairment of nutrition ; and, third, that it is usually associated with well-marked indications of tubercular disease in other organs. Hemorrhage, perforation, and stricture are not special to tubercular ulceration, and their symptoms need not now be discussed.

2. *Peritoneum*.—The symptoms which attend the progress of peritoneal tuberculosis present much variety and are often vague and misleading. Often, indeed, and not only in those cases in which the peritoneal affection is slight, or in those in which it is as it were overshadowed by the preponderance of disease in other parts, but in those cases in which it is the predominant or sole affection, they fail to indicate clearly the peritoneum as the seat of disease. Further, they are so generally complicated with symptoms due to coexisting tubercular disease in other organs, especially the lungs, pleuræ, and intestines, that it is impossible altogether to dissociate them from the latter. Most cases of tubercular peritonitis, attended with obvious symptoms, may perhaps be somewhat roughly arranged in two classes: the first (the acute class), in which the symptoms have a close resemblance to those of enteric fever; the second (the chronic class), in which the symptoms correspond for the most part with those of chronic peritonitis.

In the acute form the patient, sometimes in the midst of perfect health, more often after an indefinite period of languor and loss of flesh and strength, begins to manifest febrile symptoms attended with remissions, and indicated by heat and dryness of surface, quickened pulse, pains in the limbs, loins, and head, diminution of the secretions, and perhaps drowsiness. At the same time probably the abdomen becomes hard, tumid, tender, and uneasy or painful. Generally, also, there is disturbance of the digestive functions: dryness or furring of the tongue, thirst, loss of appetite, nausea or sickness, and constipation, diarrhœa, or irregularity of bowels. And possibly, with no material change in his symptoms beyond what may be due to increasing debility and emaciation, and the gradual supervention of 'typhoid symptoms,' the patient gradually sinks, and at the end of a few weeks dies. Among the chief points by which this affection may be distinguished from enteric fever are: the absence of rash, and of pain specially limited to the cæcal region; the probable presence of tubercular disease in other organs; and the fact that the temperature, although it may be much elevated and variable, does not present that regularity of morning remissions and evening exacerbations which are so characteristic of enteric fever.

In the chronic variety of peritoneal tuberculosis the disease sometimes commences with symptoms of acute peritonitis; sometimes it creeps on with the utmost insidiousness; but in either case the symptoms gradually merge into those of chronic peritonitis, with which (unless our diagnosis be aided by the discovery of tubercular disease elsewhere) we cannot well avoid confounding them. During the progress of the disease a more or less diffused tumour is apt to be developed (due for the most part to thickening of the great omentum), which may suggest the formation of a circumscribed abscess or a malignant growth. This, which is sometimes freely movable

under the parietes, sometimes adherent to or incorporated with them, forms occasionally a transverse bar, in a line with or above the umbilicus, occasionally a comparatively broad and thick tippet-like mass. In the last case inflammation, which usually goes on concurrently with the growth of tubercles, now and then spreads to the umbilicus, and to the skin and subcutaneous connective tissue around, and may lead to the belief that an abscess is about to point. Sometimes circumscribed abscesses form, mostly in connection with the female pelvic organs, and may either discharge themselves in the iliac regions, or open into the rectum or vagina. Ascites is very apt to ensue. The duration of fatal chronic tubercular peritonitis may vary from a month or six weeks to a year or two.

Tubercular peritonitis tends, as a rule, to a fatal result. Apparent recovery, however, is not uncommon, and there is great reason to believe that it is occasionally permanent.

*Treatment.*—The general treatment of abdominal tuberculosis is identical with that of pulmonary phthisis and generally of scrofulous disease. It comprises careful attention to hygiene, removal if need be to a more suitable climate, a good wholesome and nutritious dietary, and the use of cod-liver oil, iron, and vegetable tonics. If the mucous membrane of the bowels be specially affected and the patient be suffering from exhausting diarrhoea, treatment must of course be directed to relieve this condition. For the details of treatment in this case we must refer the reader to the articles on intestinal ulceration and dysentery. When the peritoneum is the part principally involved, abdominal pain may need to be relieved by the application of counter-irritants, fomentations, or even leeches; sleeplessness, weariness, and pain may require to be overcome by the use of opiates or other sedative or narcotic medicines; and, further, nausea, sickness, diarrhoea, and intestinal obstruction may all in turn call for relief by the various measures on which in such conditions reliance is usually placed.

---

## XI. TUMOURS

### A. Non-Malignant Tumours

These are not uncommon, but on the whole are of little medical importance.

*Pedunculated fibrous tumours* or *polypi* are sometimes very small, very numerous, and of wide distribution throughout both the small and the large intestine. Sometimes, on the other hand, they are few in number or solitary, and then often attain large dimensions. The latter are occasionally observed in the ileum, but chiefly affect the lower part of the rectum. In the former situation they are believed to be in some cases the determining cause of intussusception; in the latter they often produce irritation, bleeding, tenesmus, and other discomforts. Those only can be diagnosed and treated which are within reach, and for them removal is the only effectual remedy.

*Villous growths* are in many cases malignant. Some, however, and especially such as are met with in the large intestine, appear to be non-malignant. These usually occupy a limited and well-defined area, and sometimes encircle the bowel. The intestinal walls in the situation of the growth, and especially the mucous and submucous coats, are generally much thickened; and from this thickened area as a base, close-set, elongated, complex villi take their origin. These growths frequently cause hemorrhage, which is occasionally serious; and diarrhœa, which is sometimes of a dysenteric character. When situated near the anus they may be removed by operation.

### B. *Malignant Tumours*

*Morbid anatomy.*—Malignant growths commence sometimes in the mucous membrane of the stomach or intestines, sometimes in the peritoneal tissue, sometimes in the mesenteric or retro-peritoneal glands. In the first case, the disease usually takes its origin at some particular spot; whence it spreads over a greater or less extent of the contiguous mucous membrane, then gradually involves the whole thickness of the parietes, and having reached the serous lamina diffuses itself in a greater or less degree over it, and further implicates the mesenteric or other glands. In the second case, the growth tends rapidly to generalise itself over the surface of the serous membrane, and to infiltrate the subserous tissue; but it is often a long time before it penetrates the muscular wall of the stomach or bowels. Sooner or later, however, this is invaded at points, and then the mucous membrane becomes involved. The lymphatic glands necessarily also suffer. When the disease begins in the mesenteric or retro-peritoneal glands these gradually enlarge; and presently the morbid growth extends from them into the surrounding connective tissue, infiltrates it, and thence spreads to the serous membrane on the one hand, and to the intestinal walls on the other. It will thus be seen that, although the site in which malignant disease commences exerts an important influence over its distribution and consequences, the ultimate tendency is in each case to its general diffusion.

1. *Scirrhus cancer*, originating in the walls of the stomach or bowels, causes thickening and induration of the parts which it affects. If it attack the submucous tissue, this becomes greatly hypertrophied; and presently, the superjacent mucous membrane getting incorporated with it, its natural structure gradually disappears, and its free surface, at first perhaps thrown into rigid folds, grows irregular and nodulated. Whilst this process is going on the muscular wall becomes invaded; the morbid growth extends along the inter-muscular septa, converting them into irregular but thick vertical scirrhus bands, and the muscular tissue thus divided into strands at first hypertrophies, and subsequently undergoes fatty degeneration. At length, the subserous and serous tissues get implicated; they, like the mucous tissue, become dense, hard, and thick, and small wheal-like excrescences or nodules spring up upon the free surface. Sooner or later in the progress of the case erosion and destruction of the affected mucous

membrane takes place, and a smooth excavated ulcer results; in some cases sloughs form, and the destruction is more rapid and irregular; and frequently carcinomatous nodules sprout up from the edges and floor of the ulcerated surface. Sooner or later also adhesions form between the affected viscus and neighbouring organs, and along them the morbid process may be propagated.

Peritoneal scirrhus always commences in the form of hard, lenticular, white spots, measuring a line or so in diameter, which, though projecting above the surface, tend specially to invade the subserous tissue. They are in the first instance scattered thinly or irregularly, but soon become aggregated in parts or generally, and then coalesce so as to form patches of various sizes. These may be uniformly smooth, or may still present traces in their surface or outline of their mode of development. They rarely, however, form outgrowths, and not very often invade subjacent organs; rarely, too, do they become more than a line or two thick, except where they involve folds or processes of peritoneum. The appendices epiploicæ become converted into small hard lumps, the mesenteric and other like duplicatures thickened and indurated, and the great omentum contracted into a thick band, stretching transversely across the abdomen in the course of the transverse colon. Scirrhus cancer, indeed, whether affecting the gastro-intestinal tube or the peritoneum, tends rather to cause contraction and thickening than outgrowth, and thus, as a rule, leads to constriction of the cavities or canals which it involves, and especially therefore to constriction of the cardiac or pyloric orifice or other parts of the alimentary tube.

2. *Colloid cancer* most commonly takes its origin in the serous lamina, whence it spreads to the mucous membrane. When appearing first in the latter tissue, it causes, as other forms of cancer do, more or less considerable thickening, and manifests itself at the surface in the form of scattered masses, which have a resemblance either to the wheals of urticaria, or to groups of herpetic or eczematous vesicles. Like scirrhus, it invades the muscular coat—running along the intermuscular septa, and causing the muscular tissue to become thickened and hypertrophied; then attacks the subserous tissue and the serous membrane itself, causing these also to become thickened; and finally produces at the free aspect groups of vesicles, varying individually, perhaps, from the size of a mustard-seed to a scarcely visible point. At the mucous surface the affected patches become eroded and excavated, but remain pretty smooth, and discharge in abundance the transparent glairy fluid with which the interstices of the cancerous matrix are filled. Colloid cancer of the peritoneum, in its early stage, appears in the form of groups of vesicles, which are elevated above the general surface, and spread sometimes in tortuous and anastomosing lines as though taking the course of the lymphatic vessels, sometimes by forming scattered, isolated, more or less pedunculated growths. The morbid process tends to spread both in surface and in depth. It always involves the sub-peritoneal tissue, which may attain very considerable thickness; and it extends thence most frequently to the muscular

and mucous coats of the stomach and intestines, less frequently to the substance of the mesenteric glands, pancreas, liver, spleen, and other viscera. In extreme cases nearly the whole of the peritoneum is affected; it is then irregularly thickened—the various duplicatures being especially hypertrophied, and the great omentum either converted into a large lobulated mass, or contracted, as it is in scirrhus, into a thick, irregular, transverse band. In the progress of the disease erosion of the surface is apt to take place, and the glairy fluid which it yields is discharged in some abundance into the abdominal cavity.

3. *Encephaloid cancer*, when affecting the abdominal organs, is characterised, as it is elsewhere, by its softness, milkiness, and rapidity of growth.

If it commence in or beneath the mucous membrane of the stomach or bowel, on the one hand it soon invades the mucous and submucous tissues, and on the other spreads to the muscular coat, and through this to the tissues on the outer aspect of the viscus. The extension of the growth both in thickness and in surface is usually very rapid, and before long results in the formation of a lobulated tumour, which often attains a very considerable bulk. The encephaloid mass is of course liable to undergo all those interstitial changes to which encephaloid cancer is usually liable; but especially it tends to ulcerate. Ulceration begins, as a rule, early, and is almost invariably attended with sloughing of the cancerous mass, which becomes consequently deeply and irregularly excavated. But while this is going on the edges of the ulcerated chasm still furnish lobulated outgrowths, and moreover such outgrowths not unfrequently take place from the ulcerated surface itself. In some cases encephaloid tumours give rise from their mucous aspect to a pile of highly vascular villous outgrowths, constituting the so-called ‘villous cancer.’ Encephaloid cancer of the peritoneum appears in the form of discrete nodular outgrowths, which are small and rounded, and differ from those of scirrhus not only in their greater softness but in their greater prominence. They are hemispherical, spherical or pyriform, and often distinctly pedunculated. In its further progress encephaloid cancer presents great varieties. In some cases it seems, like scirrhus, to invade more particularly the substance of the peritoneal folds and to involve subjacent organs; and under such circumstances we sometimes find the mesentery converted into a thick, plicated, cancerous mass, with the cancerous growth extending from the mesenteric attachment over the surface of the intestines, or the greater or lesser omentum or the subperitoneal tissue of other regions affected in like manner. In other instances it tends rather to form outgrowths which may be small and clustered, or discrete, rounded, and massive. In the former case the whole peritoneal surface may be found beset with small lobulated or bunch-of-currant-like excrescences, and the great omentum converted into a large loose mass of such bodies. In the latter case the tumours, though still probably abundant, are isolated; and, while many no doubt are small, others attain the size of an orange, or even a child's head. So far as we know, the

melanotic variety of encephaloid cancer always manifests itself in the latter form.

4. *Epithelioma* affects the rectum and anus almost exclusively. It is sometimes of primary origin, sometimes due to extension from the uterus or vagina.

5. *Adenoid cancer*, or cylindrical epithelioma, which has a close resemblance to encephaloid, is not uncommon in the intestine. It is probably more common than any as a primary disease of the mucous membrane, and is especially apt to cause stricture.

6. *Sarcomatous and lymphadenomatous* growths may be regarded clinically as mere varieties of encephaloid cancer. Still they present some peculiarities of habit. Sarcomatous growths are exceedingly uncommon, and arise mainly in the substance of the walls of the stomach, where they constitute tumours of considerable size, which tend to ulcerate, and comport themselves generally as do encephaloid tumours. Lymphadenoma is especially a disease of the lymphatic glands and textures; and hence, when the abdominal organs are its seat, the abdominal glands usually reach an enormous volume, and the spleen undergoes more or less considerable enlargement. In its further progress the morbid growth involves the connective tissue around the already diseased glands; and hence the substance of the mesentery and other similar folds of the peritoneum become thickened and infiltrated, and nodular outgrowths sometimes appear upon their surfaces. As the affection still progresses the morbid growth creeps from the mesenteric attachment on to and around the small intestine, confining itself almost, if not quite, exclusively to the peritoneal membrane and subperitoneal tissue; and thus the intestine, while remaining pervious and probably healthy as to its mucous membrane, becomes converted into a thick-walled rigid cylinder. The large intestine and even the stomach may be similarly affected.

Whenever carcinoma or any other form of malignant disease affects the peritoneum, stomach, or bowels, it may spread by continuity to almost any neighbouring organ; and hence the liver, pancreas, and spleen are liable to be invaded when the stomach or peritoneum in the vicinity is its seat, and the various pelvic organs when the rectum is diseased; and further, the mesenteric and retro-peritoneal lymphatic glands, or some of them, when secondarily affected, often develop into large tumours. Such tumours are produced most rapidly, and attain their largest dimensions, when the disease to which they are secondary is some soft form of malignant disease.

There are certain parts of the gastro-intestinal tube which are more liable than others to be the primary seat of malignant disease. They are the stomach and certain tracts of the large intestine. Of these the stomach is much the most frequently affected; and, although no portion of its surface enjoys absolute immunity, there is no doubt that its pyloric extremity most frequently suffers. When the cardiac orifice is the seat of disease, the adjoining portion of the œsophagus is commonly affected. When the pylorus suffers, the morbid process usually encircles that

portion of the stomach which adjoins it, but rarely extends into the duodenum. The effect of malignant disease upon the stomach is in many cases to cause irregular contraction and deformity, and especially to cause stricture at the cardiac or pyloric orifice. If the pylorus be alone affected and resist the onward transmission of food, the stomach often becomes preternaturally dilated; if, on the other hand, there be impediment to the entrance of food from the œsophagus, the organ necessarily shrinks. Of the large intestine, the parts most liable to suffer primarily are first, the rectum, and second, the sigmoid flexure; and here, as at the orifices of the stomach, the disease tends to circumscribe the tube and to cause stricture. The cæcum not unfrequently suffers. It may be added that while all parts of the gastro-intestinal canal are apt to be implicated in the progress of malignant disease commencing in the peritoneum or lymphatic glands, the lower part of the rectum is especially liable to become involved in the extension of uterine, vaginal, or other pelvic growths. Further, it must not be forgotten: that malignant disease, whether of the stomach or bowels, may be attended with rupture into the peritoneal cavity or the establishment of communications between adjoining hollow organs, such as between the stomach and transverse colon or between the rectum and bladder or vagina; that hemorrhage (sometimes profuse), with foul or fetid discharges, is apt to take place from the congested or ulcerated mucous surface; and that (especially when the peritoneum is largely involved) peritoneal inflammation, ascites, or obstruction to the return of blood from the lower extremities, frequently supervenes.

Of the various forms of malignant disease affecting the organs under consideration, scirrhus is undoubtedly the most common; scarcely any of them, however, is absolutely rare. Taking all forms together, it may be said that, though they occur at all ages and even in children, they mostly occur after the age of forty—a rule, however, which is more absolute as regards primary gastric or intestinal disease than that of the peritoneum; indeed, malignant disease of the peritoneum (especially in connection with similar affection of the ovaries) is not uncommon in young adult females. Sex, on the whole, exerts but little influence numerically. Carcinoma of the stomach is one of the most frequently fatal forms of malignant disease.

*Symptoms and progress.*—The symptoms referrible to malignant disease of the several organs now under review simulate those of the inflammatory (mainly chronic) affections of the same organs. And the differential diagnosis between them often depends, less on the presence or absence of specific symptoms, than on a careful consideration of the history of the case and a close observance of the phenomena which it presents, and their relation to one another. Thus malignant disease of the stomach has many features in common with chronic gastritis and gastric ulcer; malignant disease of the bowels many in common with chronic ulceration of the bowels and its various sequelæ; and malignant disease of the peritoneum many which it shares with chronic peritonitis, tubercular peritonitis, and even simple ascites. But malignant disease is always remarkably insidious in its progress; and vague symptoms of

ill-health, with loss of flesh and strength, usually manifest themselves long before the patient quite recognises the fact that he is ill, or can quite define the character of his sufferings. The patient, therefore, is generally ill and often markedly cachectic before the specific signs of gastric, intestinal, or peritoneal mischief reveal themselves. Again the course of a case of malignant disease is always progressively from bad to worse; and this progressively downward tendency is connected, as a rule, not simply with the aggravation of the ordinary symptoms due to progressive impairment of function of the organ primarily affected, but with the supervention of complications connected with the special properties of malignant disease, such as the involvement of the liver and other abdominal organs in the morbid growth and the development of disease in more remote organs. The appearance of a tumour and its manifest increase in bulk and change in form, in association with the various phenomena above enumerated, leave little room for doubt. Febrile symptoms, thirst, and dryness or foulness of tongue are no necessary accompaniments of the disease.

1. *Stomach.*—The special symptoms of malignant disease of the stomach are as various as those of ordinary dyspepsia. They comprise mainly loss or capriciousness of appetite, pain, and vomiting. Anorexia is a very constant and ordinarily a very early symptom; but it is variable in its presence, and is sometimes absent from first to last. Occasionally the appetite is excessive. Uneasy feelings (weight and fulness) in the region of the stomach are frequently complained of, especially after taking food. In most cases also there is absolute pain, variously described as aching, burning, cutting, or stabbing, and referred either to the epigastrium or interseapular region or to other neighbouring situations. This comes on in paroxysms, which are probably at first ‘few and far between,’ but increase in frequency, duration, and severity with the progress of the disease. It is often brought on or increased by the ingestion of food, or by pressure applied to the epigastrium. Pain, however, like anorexia, is sometimes of little severity, and occasionally wholly wanting. Eructation is a common but unimportant symptom. Vomiting, however, supervenes sooner or later in the great majority of cases. This is mostly caused by the taking of food, and comes on at different periods after it: if the cardiac orifice be contracted the food is usually returned at once or after a short time (as in other forms of œsophageal obstruction) by regurgitation; if the pylorus be affected the vomiting is often delayed for an hour or two or more than that; when the stomach is irritable vomiting may (as in gastric inflammation) take place almost immediately after food has entered it. The vomited matters in the earlier periods of the disease are chiefly altered ingesta combined with mucus and the acid secretions of the stomach. Later on (especially if ulceration have taken place) small quantities of blood escape from the diseased surface, and, mingling with the contents of the stomach, give to the vomited matters a sooty or coffee-ground appearance. The persistence of this kind of vomit is very characteristic of gastric carcinoma. Profuse discharge of blood, with hæmatemesis and

melæna, occasionally takes place, but is not nearly so frequent relatively as it is in cases of simple ulcer. When sloughing occurs, the vomited matters are often extremely offensive. It is very common, especially when the pylorus is the seat of disease, for them to contain *sarcinæ* and the *torula cerevisiæ*. The detection of a tumour depends partly on its size and partly on its situation. A tumour at the cardiac orifice or cardiac extremity can rarely be felt, however large or extensive it may be; and one situated in the posterior wall or lesser curvature is less easy of recognition than one occupying the anterior surface or the larger curvature or the pylorus. The situation of perceptible (mostly pyloric) tumours varies somewhat. They usually occupy the epigastric or right hypochondriac region, but are not unfrequently found in the neighbourhood of the umbilicus, and occasionally indeed, lie to the left of the umbilicus or even in the right iliac region or in the hypogastrium. Unless they have become firmly adherent to the abdominal walls in front, or have blended with the pancreas or other enlarged glands behind, they are usually movable to some extent under the abdominal walls, both during the act of forced inspiration and (if the patient is lying down) in rotation of the body from side to side. They are often irregular in shape, generally very hard, and not unfrequently lifted up with the aortic pulsations. They are usually also resonant on percussion. Constipation is almost always present, and occasionally for a time is the most prominent symptom. Its completeness and persistence may even lead to the case being mistaken for one of intestinal obstruction. The special symptoms which ensue when rupture of the stomach into the peritoneal cavity takes place are those of sudden acute peritonitis; the special signs of a communication with the transverse colon, are the occasional vomiting of actual *fecæ* and the discharge of undigested food from the bowel.

2. *Bowels*.—The symptoms referrible to malignant disease of the bowels are yet more vague in their indications than those which attend gastric carcinoma. There is generally irregularity of action, sometimes looseness, sometimes constipation, and it may be the occasional discharge of mucus or modified blood. At the same time there is often pain: partly of a colicky character and connected with unwonted movements of certain portions of the bowels; partly burning, aching, or cutting, and referrible to some particular region. Malignant disease of the large intestine, and more particularly of the sigmoid flexure and rectum, produces, as a rule, more or less impediment to the action of the bowels, and finally stricture. In this case also, associated with symptoms of obstruction (preceding them, accompanying them, or following them), mucous, sanguinolent, purulent, and fetid discharges, occasionally even profuse hemorrhages, occur. Further, if the rectum be the seat of disease, the case is apt in its progress to be complicated by the formation of communications between the bowel on the one hand, and the vagina, bladder, or urethra on the other, and the consequent discharge of *fecal* matter and gas from these parts. In malignant disease of the bowels, equally as in malignant disease of the stomach, the presence of a distinct permanent

tumour is a fact of capital importance. Such a tumour always soon becomes obvious when the cæcum is the seat of disease, but in other cases often fails of recognition; moreover, phantom tumours, due to accumulation of flatus or fæces, are in such cases specially apt to arise and disappear from time to time and puzzle the physician. When the lower part of the rectum is affected, the presence of a tumour may generally be readily detected by digital examination per anum.

3. *Peritoneum and glands.*—The symptoms of peritoneal and of glandular malignant disease are necessarily very various and easy to be misunderstood. These affections are in a large proportion of cases associated with similar disease of the stomach, bowels, liver, uterus, or ovaries, and not unfrequently supervene upon them; and hence their special symptoms are liable to be confounded with and masked by those of the latter lesions. On the other hand, many of the symptoms commonly attributed to malignant disease of the stomach and other abdominal organs are strictly referrible to involvement of the peritoneum and lymphatic glands. Among the symptoms which attend the affections now under discussion must be enumerated nausea, vomiting, loss of appetite and constipation, diarrhœa, or irregularity of the bowels, together with abdominal uneasiness and pain. The most significant point, however, is the progressive enlargement of the belly with the presence of a growing tumour or tumours. These present all varieties of character; they may occur in any region; may be movable or fixed; may vary in size and shape; may be hard and resisting, or soft and almost yielding a sense of fluctuation; and, especially when they are developed in the neighbourhood of the celiac axis and superior mesenteric artery or over the aorta, may pulsate as distinctly as many aneurysms do. And hence, notwithstanding the important evidence which their presence furnishes, they may be confounded, at some stage at least of their progress, with circumscribed abscesses, hydatid tumours, floating kidneys, or even aneurysms. In cases where (even if the malignant growth be very abundant) the individual tumours are small, the presence of peritoneal outgrowths may altogether escape detection. We may draw attention to the fact that often, when no other signs of tumour are distinguishable, the presence of the thickened and contracted great omentum, which has been shown to occur so frequently in scirrhus and colloid cancer, may be recognised as a more or less irregular bar extending horizontally from under the margins of the left ribs across the upper part of the umbilical region to the neighbourhood of the umbilicus. In the progress of the disease the peritoneal affection often becomes complicated by ascites, peritonitis of a sub-acute character, involvement of the gastro-hepatic omentum with obstruction of the vena portæ or common bile-duct, and consequent jaundice, or anasarca of the lower extremities; and occasionally also the kidneys get affected, the ureters obstructed, or the pelvic organs involved.

*Treatment.*—The treatment of the above affections can unfortunately only be palliative. When symptoms are chiefly referrible to the stomach they must be treated, and may for a time be benefited, by such measures

as have been recommended for gastric ulcer. When the intestines mainly are involved, diarrhœa may need to be restrained by astringent medicines, constipation to be overcome by mild laxatives, such as castor oil and the like, or by enemata. And pain, whatever its seat or source, may often be relieved by counter-irritation, fomentations, or leeches. Opium in such cases is generally invaluable, and in most cases becomes at length indispensable—relieving discomfort and pain, soothing the mind, and giving sleep. The patient should of course be sustained by appropriate aliment in sufficient quantities and, if necessary, by stimulants. The quality of the food and the mode of its administration must be determined by the special requirements of the case; but generally it should be wholesome, easily digestible, and administered in small quantities and at frequent intervals. Milk, eggs, beef-tea, broths, fish, and the like are among the most suitable articles of diet. In some cases of cancer of the pylorus and of the cæcum excision of the affected parts has been performed with temporary benefit.

---

## XII. ANIMAL PARASITIC AFFECTIONS

### A. *Tape-worms and Cyst-worms* (*Cestoda* or *Tæniada*)

#### 1. *General Account*

The general term cestoda or tæniada includes tape-worms and cyst-worms. Of these, though many species are known to exist, four only are of interest and importance to the practical physician. They are the *tænia solium*, *tænia mediocanellata*, *tænia echinococcus*, and *bothriocephalus latus*, with their respective cystic representatives.

All the tæniada pass through two phases of existence. In the one the characteristic head or *scolex* of the animal, developed in connection with a cyst or bladder-like body, and devoid of sexual organs, lies imbedded in the solid tissues of the *host*, or creature that harbours it. In the other, the animal, or rather colony of animals, in the form of a tape-worm or *strobilus*, occupies the alimentary canal. In this condition it still presents at its upper extremity a scolex or head by which it adheres to the mucous membrane, while its tape-like body is divided into a series of quadrilateral elements, or *proglottides*, each of which when mature contains male and female organs, and must be regarded as a distinct animal. To trace the cycle of events in the life history of the tæniada it will be convenient to commence with the ripe proglottides, within which are produced enormous numbers of fertile eggs, in the interior of each one of which a peculiar six-hooked embryo is developed. These proglottides usually become detached from the rest of the strobilus, escape from the anus of the host, and either then or previously discharge their ova, which become scattered broadcast. Of these fertile ova some find their way sooner or later into the alimentary canal of some appropriate animal. Then the six-hooked embryo bursts its shell, migrates through the intes-

tinal parietes, and continues its wanderings until it reaches some spot suitable for its further development, where it gradually undergoes those changes which result in the formation of the perfect cystic scolex. The further fate of this scolex depends mainly on that of its host. It cannot migrate, but lies passive in the cavity which it forms for itself, and there at length perishes unless before that occurrence its host become the prey of some other animal. In this event the scolex enters the alimentary canal, and under the new conditions which then surround it at once enters on a new career of life. It fixes itself to the mucous surface, it loses its vesicular expansion, and from its caudal extremity the strobilus or chain of sexually reproductive proglottides is gradually evolved. Thus two distinct hosts as a rule are needed for the completion of the cycle of existence of these creatures; the one (usually a vegetable feeder) for the asexual period of its existence, the other (very commonly a carnivorous animal) for the period of its sexual activity. It follows from the above statements that the ova of the tape-worm, even if set free within the alimentary canal, probably never get hatched until after their escape from it. Further, it may be regarded as a general rule, that the same species of animal is not liable to suffer from both the cystic and the sexual forms of the same cestode. Man is in some degree an exception, for he is apt to harbour both the *tænia solium* and its vesicular representative—the *cysticercus cellulosæ*. Considering, however, that patients affected with this tape-worm are not usually also affected with the *cysticercus*, and conversely, and that man, moreover, is an omnivorous feeder, there is good reason to believe that the exception is apparent rather than real, and that he derives the two forms of the parasite in the orthodox way from independent sources.

## 2. *Tænia Solium*, *Tænia Mediocanellata*, and *Bothriocephalus Latus*

a. *Tænia solium* and *Cysticercus cellulosæ*.—The *tænia solium* is one of the most common of human tape-worms. In its perfect condition it usually measures from seven to ten feet long, but often exceeds that length. Its head or scolex, which is about as large as a small pin's head, or, to be more exact, between  $\frac{1}{45}$  and  $\frac{1}{35}$  inch in diameter, is succeeded by a delicate thread-like neck, which, gradually becoming broader and flatter and wrinkled transversely, merges ere long in the distinctly jointed body. The joints or proglottides are, in the first instance, much broader than they are long; but gradually with their increase in size this relation ceases; and although they still get broader, their length throughout the greater part of the strobilus exceeds their breadth. Towards the lower extremity, the quadrilateral joints measure on the average a quarter of an inch wide by half an inch long. The globose head presents four projecting suckorial discs placed at equal distances upon and a little above the equator; and springing from its pole a rounded elevation, or *rostellum*, the margin of which is furnished with a double circle of hooks. The apparently homogeneous neck may be seen under the microscope to be transversely wrinkled at a very short distance from the head. The

sexual apparatus becomes first visible about a foot below. It comprises male and female organs opening by a common aperture in the lateral edge of each joint—the apertures of the successive proglottides occupying alternately opposite sides. At about two feet from the head, the ova become impregnated, and shortly afterwards enter the uterus, which occupies a large portion of the body of the proglottis, forming a longitudinal central canal with several horizontal diverticula on either side. The egg is globular, about  $\frac{1}{700}$  inch in diameter, presents a remarkably thick brownish shell, both concentrically and radially striated, and when ripe contains a six-hooked embryo.

The *tænia solium* is essentially an inhabitant of the small intestine, to the mucous surface of which it fixes itself by its hooklets and suckers. It is usually, as its name implies, solitary; but two, three, or more, are not unfrequently associated, and occasionally much larger numbers. From the time of its entrance into the bowel until it reaches its full development a period of three or four months usually intervenes; and it may live in the bowel for many years, during which time it is constantly shedding its ripe proglottides and discharging ova into the alimentary canal.

The *cysticercus cellulosæ* is chiefly known as a denizen of the flesh of pigs, in which it is sometimes present in vast numbers, rendering the pork 'measly.' And it is almost exclusively to the use of such pork in an uncooked or imperfectly cooked condition, that the development of *tænia solium* in the human intestine is due. In the comparatively rare cases in which the *cysticercus* infests the human body, it seems

to occur mainly in the muscles, connective tissue, brain, eye, and serous membranes. It exists under the form of a round or ovoid vesicle, about the size of a pea or bean, but sometimes attaining that of a marble, formed of a transparent elastic membrane, containing a clear limpid fluid. Springing from one side of this vesicle is a wrinkled cylindrical neck,

FIG. 58.—TÆNIA SOLIUM AND CYSTICERCUS.

*a, b, c, d.* Different parts of Tape-worm (Nat. size). *e, f.* *Cysticercus cellulosæ* (Nat. size). *g.* Head of *Cysticercus*  $\times 25$ . *h.* Head of ditto from above  $\times$  about 50. *i.* Sucker  $\times 250$ . *j.* Hooklet attached  $\times 250$ . *k.* Egg  $\times 250$ .

terminating in a head precisely similar to that of the *tænia solium*. The neck and head protrude externally after death, and may be made to protrude by pressure during life; but in the ordinary living state they are retracted within the vesicle, lying coiled up against one side of it. The conversion of the six-hooked embryo into the perfect cystic scolex occupies about two and a half months; and the scolex may remain living in the tissues of its host for many years.

*b. Tænia mediocanellata*, and *Cysticercus tænia m. c.*—This tape-worm, which was formerly confounded with the last, is equally common. It presents a general resemblance to it both anatomically and in habit; but it presents also characteristic differences. It attains a greater length, its joints are longer and broader, and its head also is two or three times as thick. The head, moreover, is furnished with four large round pigmented suckers, but with neither rostellum nor armature of hooklets; the

FIG. 59.—*TÆNIA MEOCANELLATA*.

FIG. 60.—*BOTHRIOCEPHALUS LATUS*.

*a, b.* Different parts of Tape-worm. *c.* Head  $\times 10$ . *d.* Egg  $\times 250$ .

uterus, though exhibiting the same general arrangement as that of the *tænia solium*, is characterised by much more numerous and finer transverse processes; and the ova, instead of being round, are oval, the long diameter differing little from the diameter of the egg of the *tænia solium*, the short diameter measuring about  $\frac{1}{850}$  inch.

The *cysticercus* of this tape-worm seems especially to affect the ox, and it is, therefore, to the eating of imperfectly cooked beef that the introduction of the scolex into the intestines is due. The *cysticercus* is a small oval vesicle, similar to that of the *cysticercus cellulosæ*, but smaller than it, and furnished with a neck and head, of which the latter is identical with that of the adult sexual strobilus. It is not known to affect the human being.

*c. Bothriocephalus latus.*—This tape-worm is limited in its range to

certain European countries, especially Belgium, Holland, Poland, Prussia, Russia, Sweden, and Switzerland. It is the largest of all tape-worms—not unfrequently attaining a length of twenty-five feet and upwards, and a breadth of more than half an inch at its widest part. The head is ovoid in form, measuring about  $\frac{1}{16}$  inch in length by  $\frac{1}{26}$  in breadth, and presenting two opposite longitudinal deep grooves or suckers, but no hooklets. The neck, which is comparatively narrow, soon becomes transversely wrinkled; and as it widens out and retreats from the head, the wrinkles divide it into successive segments. The segments gradually increase in all their dimensions, but for the most part continue of greater width than length, and are specially characterised, not merely by their general form, but by the facts that the genital pore is placed in the centre of each flat surface, and that the uterus forms a small rosette, of which this pore is the centre. The ova never become matured within the uterus, and usually escape thence into the bowel, while the proglottis is still a portion of the strobilus. After the discharge of their ova, the joints diminish in size, and become shrivelled and elongated. The eggs are of oval form, measuring about  $\frac{1}{376}$  inch by  $\frac{1}{576}$ , and have a firm brown shell, which opens by a lid at one end. The embryo on its escape from the egg is provided with cilia, which it soon loses, and then presents the common six-hooked character. The cysticercus of this tape-worm has long been believed to infest some fish or other aquatic animal. The correctness of this surmise has been established by Dr. Braun,<sup>1</sup> of Dorpat (a locality where the worm is comparatively common), who, on examining the fish brought to market, discovered that the muscles, with the liver and other viscera, of the pike and eels were in large proportion abundantly infested with the scolices of this parasite. Moreover, on feeding dogs and cats with the infected tissues, bothriocephali were developed in their bowels.

*Symptoms.*—The symptoms to which tape-worms give rise are on the whole trivial and unimportant. Many of those who are infested by them enjoy perfectly good health; and many more make them the scapegoats of all the ailments (imaginary or other) from which they happen to suffer during the residence of these parasites within them. Among the symptoms which are referred to their presence are: pain and discomfort in the belly, capricious appetite, variable condition of bowels, itching at the nose and anus, depression of spirits, emaciation, and hysterical, epileptic, or other nervous phenomena. The list might easily be extended, but when we consider that, notwithstanding all the evil influences which have been attributed to them, they are probably never diagnosed or even suspected to be present until their joints have been detected in the stools, it is obvious how vague and on the whole how apocryphal all these influences are. The only way in which the presence of tape-worms can be recognised is by the discovery of their joints either in the stools or about the anus or on the body-linen, and of their eggs by the microscopic examination of the fæces.

<sup>1</sup> Virchow's *Archiv*.

The *cysticercus cellulosæ* causes no symptoms unless it be lodged in some delicate or vital organ, such as the eye or cortex of the brain, and even then the symptoms are not specific.

*Treatment.*—Many remedies have been employed for the purpose of getting rid of tape-worms; but those on which reliance is now chiefly placed are the male fern, the bark of the pomegranate root, kousso and kamala. The liquid extract of male fern may be administered in a dose of from 30 to 120 minims early in the morning on an empty stomach, and be followed shortly by a full dose of castor oil. And if this procedure prove insufficient, the treatment may be repeated either on the next day or from time to time at short intervals. The other varieties of vermifuge are employed in much the same manner. The decoction of pomegranate root is given in large quantities—a pint or more, for example—in two or three portions at short intervals. Kousso is administered similarly, excepting that the powder from which the infusion is made is usually drunk with the infusion. The dose of this is from four to eight ounces. These drugs rarely fail to bring away large portions of the worm; but no absolute cure is effected, unless the head be brought away as well. This, however, from its small size, is very apt to escape detection. It is consequently of great importance to make a careful inspection of the evacuations which are passed subsequently to the administration of vermifuge drugs. In order to prevent the development of tape-worms in the intestine, it is necessary that flesh, and especially those kinds of flesh which are known to harbour their vesicular representatives, should always be eaten in a well-cooked condition. Underdone and merely smoke-dried beef and pork should certainly be avoided.

With respect to the *cysticercus cellulosæ*, unless it occupies some superficial part, and thus lies within reach of surgical treatment, we can do nothing for the patient's relief. The ova of the *tænia solium* are probably taken into the stomach with uncooked vegetables, salads, and the like, and hence those who wish to guard against them should content themselves with cooked vegetables only.

### 3. *Tænia Echinococcus* and *Hydatid*

The *tænia echinococcus* is only known to affect the dog and the wolf, and is usually found in them in large numbers, adhering to the mucous membrane of the duodenum and jejunum. It is peculiar in comprising in its perfect form four joints only, and in having a length of little more than a quarter of an inch. The first joint is that which includes the head. This measures about  $\frac{1}{100}$  inch wide, and is furnished with four suckers, and a central rostellum, provided with a double coronet of hooks, which vary from thirty to forty in number. The fourth segment, which is as long as the other three joints together, is usually alone furnished with sexual organs and a marginal reproductive papilla. The eggs, like those of the *tænia solium*, are globular and thick-walled.

The *cysticercus* or larval form of this tape-worm, commonly known as

an *hydatid*, is one of the most dangerous to life of all parasites. It differs from the cysticerci of other tape-worms in the fact that it is capable, on the one hand, of almost indefinite increase of size, on the other of almost indefinite multiplication by the formation of gemmæ. Its favourite haunt is the liver, next to that the subperitoneal tissue, and then probably the lungs, kidneys, and brain. It is found also in the heart, muscles, and bones; and indeed has occasionally been detected in almost every organ and tissue of the body. In its early condition it is a small globular cyst, with transparent laminated walls and finely granular contents. At a later stage the cyst has acquired considerable dimensions, the walls have become thick and the contents fluid. The walls are formed of two portions, an outer, comparatively thick, which is transparent, elastic, tremulous, and beautifully laminated; an inner, which is thin, delicate, and composed mainly of delicate cells, often containing oval or globular refractive bodies. The fluid contents are limpid, colourless, of low specific gravity, and peculiar in containing a considerable quantity of salt, and, as a rule, no

FIG. 61.—TÆNIA ECHINOCOCCUS.  
a. Tænia  $\times 10$ . b. Ovum  $\times 250$ .

FIG. 62.—HYDATID CYST  $\times 100$ .

albumen. In some cases the hydatid experiences no other change than increase of size. Much more commonly, however, it undergoes further development. This consists principally in the formation of other cysts in the substance of its walls, sometimes towards the outer aspect, sometimes in the mid-region, sometimes towards the inner aspect, and then often in connection with the cellular lamina. These secondary cysts in many cases repeat in their growth all the characters of the parent hydatid. In many they remain permanently devoid of the outer laminated wall. But whether they continue thus simple or not, and especially in the former case, their contents often undergo gradual conversion into one or several echinococci or scolex heads—the cysts then forming what are sometimes termed brood-capsules, and remaining permanently of minute, if not microscopic, size. The results of these processes going on almost indefinitely are very various. Thus, in some cases, an hydatid tumour as large, perhaps, as a child's head, consists of one hydatid cyst only, with a larger or smaller number of brood-capsules, springing bud-like from its inner surface; in other cases an indefinite production of barren hydatid cysts takes

place, so that the original cyst becomes filled with innumerable daughter cysts, each of which has, like its parent, the capacity for growth and the production of new cysts by gemmation; in other cases again (and these are the most common) the parent hydatid ultimately contains both barren and fertile cysts. Occasionally the hydatids formed in the walls of the primary cyst, instead of projecting at its inner surface, and finally getting shed into its cavity, project outwards and thus form separate tumours; and occasionally also, in the liver, the hydatid growth forms a multilocular mass, in which it may be assumed that the walls of the separate cysts are, as it were, fused together.

The scolex or *echinococcus* in its living condition is a rounded or ovoid body from  $\frac{1}{120}$  to  $\frac{1}{200}$  inch in length, attached by a depression at one extremity to a cord which fixes it to the wall of the brood-capsule, and presenting at the other extremity an orifice communicating with a central vertical canal, at the bottom of which lie the retracted rostellum and hooklets, and on the sides of which is seated the inverted suetorial region. When the animal is dead all the latter organs are protruded, and the form which it then presents is as nearly as possible that of the first joint of the *tænia*; the small vesicular body is surmounted by a kind of quadrilateral expansion, the angles of which are occupied by suckers and from the centre of which arise the rostellum and the crown of hooklets. The latter vary in length between  $\frac{1}{780}$  and  $\frac{1}{830}$  inch. The growth of hydatids is for the most part very slow; they enjoy, however, a long life, often continuing to grow and multiply for five, ten, fifteen years or more, and it may be during the whole period of the life (however much pro-

longed) of their host. In many cases, however, they (like all other imbedded parasites) undergo spontaneous dissolution; in which case the tumours shrink; the cyst walls get flattened and compressed against one another; the echinococci break down, shedding their hooklets; the surrounding tissues become thickened and indurated; and an abundant deposit of calcareous matter pervades the capsule and even the hydatid mass.

For the *symptoms* and *treatment* of hydatid tumours we

FIG. 63.—ECHINOCOCCI.

a. Group of Echinococci still attached to ruptured brood-capsule  $\times 100$ . b. Hooklets  $\times 500$ .

must refer to the diseases of the several organs in which they occur. We need only mention here that no drug that we know of given by the mouth is capable of affecting these creatures injuriously; and that, in reference to prophylaxis, the chief if not sole source from whence we derive them is the excrement of dogs.

B. Round-worms (*Næmatoda*)

## 1. General Account

These are elongated round worms, presenting a distinct integument marked with fine transverse rugæ, a perivisceral cavity, a distinct alimentary canal, provided with a mouth at one extremity, and for the most part an anus on the ventral aspect close to the opposite extremity, and sexual organs. The sexes are always separate; in the male (which is smaller than the female) the genital pore opens in immediate relation with the anus; in the female, the vaginal orifice is usually situated about the middle of the ventral aspect.

It is certain that some species of this sub-class of parasites need (like the *tæniada*) two successive hosts for the completion of their cycle of existence. The *trichina spiralis*, for example, passes an asexual life imbedded in the voluntary muscles of the pig or man; and there, unless the affected flesh become the food of some other animal, after a while it dies. If, however, the trichinous flesh be eaten, the cysts in which the trichinæ are contained become dissolved; the animals are set free, rapidly acquire sexual organs and copulate; ova are developed and fertilised and hatched while still in the uterus: and the living embryos on their birth, instead of remaining in the bowel, undergo an active migration through its walls and ere long reach the tissues in which they are to become imbedded. As regards the *ascaris lumbricoides*, there is good reason to believe: not only that the ova which are shed in vast numbers into the intestinal canal are never hatched there; but that they are taken into the body of some other animal, probably one of the invertebrata, within which (possibly imbedded in the parenchyma) the worms complete one phase of their existence. There is reason even to doubt whether the common thread-worms multiply in the region which they infest—whether the ova which they discharge so abundantly become hatched within the anus. Dr. Ransom, indeed, suggests that in many cases (among young children especially) there may be a kind of reinfection due to the conveyance of the ova from the anus to the mouth by the fingers.

Among the *næmatode* worms are included the *Ascaris lumbricoides*, the *Oxyuris vermicularis*, the *Dochmius duodenalis*, the *Trichocephalus dispar*, the *Trichina spiralis*, and the *Filaria sanguinis hominis*, which will now engage our attention; the *Filaria medicinis*, whose effects are surgical; and several others, including the *Strongylus gigas*, which are of rare or doubtful occurrence in man.

2. Common Round-worm (*Ascaris Lumbricoides*)

This well-known worm varies in size: in the female from 10 to 14 inches long, and from  $\frac{1}{4}$  to  $\frac{1}{3}$  inch thick; and in the male from 4 to 6 inches long, with a correspondingly small diameter. The worm is cylindrical, tapering to either end, white with a brownish or reddish tinge, and

invested in a firm elastic integument. The ova, of which each female discharges, on the average, 160,000 daily, are oval, measuring  $\frac{1}{320}$  inch by  $\frac{1}{440}$  inch. They have a thick, firm, nodulated shell, and contain, as ordinarily passed from the bowel, no trace of embryo.

This ascaris is found in some few animals besides man. In man its special habitat is the small intestine; but it is apt to wander, and thus to reach the colon on the one hand, or the stomach on the other; and, indeed, it has been known to find its way into the hepatic or pancreatic duct, and also into the nose or larynx. It has been asserted that it occasionally perforates the wall of the bowel, and thus finds its way into the peritoneum, or some sinus or abscess. It is now, however, generally held that when found in such situations it has simply passed thither through an accidental perforation. The number of ascarides present at the same time rarely exceeds five or six. But authentic cases are on record in which the bowels have been infested with hundreds and even thousands of them. The time during which a worm remains a denizen of the bowels is probably never more than a few months.

*Symptoms.*—Innumerable symptoms have been referred to the presence of these parasites, as to that of the tæniæ; but there is no doubt that in the great majority of cases they give no indication whatever of their presence, which is not even suspected until one or more have been discharged. The symptoms which might reasonably be referred to them are those of intestinal irritation, which in children are always liable to be attended with some degree of fever and cerebral disturbance. When these worms are harboured in large numbers there is no doubt that they may induce very grave gastro-enteritic symptoms, but symptoms which are in no sense characteristic. Occasionally, too, a mass of them causes complete occlusion of the bowel, as any other concretion may do. In all cases where these worms are suspected to be present, and always before a cure can be safely announced, the fæces should be subjected to microscopic examination; when, if they be present, the innumerable eggs which are discharged can scarcely be overlooked. Ascarides are occasionally vomited.

*Treatment.*—Various remedies have been employed with the object of getting rid of

FIG. 64.—ASCARIS  
LUMBRICOIDES  
(Nat. size).

FIG. 65.—Egg of  
Ascaris Lumbricoides  
x 250.

ascarides, and among them those which are in common use against tapeworms. The mucuna pruriens also was formerly much esteemed. The remedy now mainly relied upon is santonica, and more especially its active principle, santonin, of which from one to three grains may be given twice

daily to a child, and about twice that quantity to an adult. Violent purgatives are of little or no use; an occasional laxative may, however, be given with advantage during the course of treatment by *santonin*.

### 3. *Common Thread-worm or Seat-worm (Oxyuris Vermicularis)*

This creature is minute, fusiform, white, and, as its popular name implies, thread-like. The female varies from  $\frac{1}{3}$  to  $\frac{1}{2}$  inch in length, and presents a comparatively long attenuated caudal extremity. The male is about half the length of the female, and its caudal extremity is simply fusiform. The eggs are oval, but unsymmetrical, measuring  $\frac{1}{490}$  inch by  $\frac{1}{1100}$ . They present a firm shell with three laminæ, of which one is absent at one of the poles. At the time of deposition they contain a developing embryo. Thread-worms are probably the most common of all intestinal parasites; they infest persons of all ages, but children much more frequently than adults. They occur habitually in the colon alone, and indeed are limited almost exclusively to the rectum. They are often present in enormous numbers. The females are apt to migrate through the anus, and to deposit their eggs on the skin and among the hairs in its vicinity; they occasionally also find their way into the vulva, vagina, and urethra.

*Symptoms.*—The chief symptoms to which oxyurides give rise is troublesome itching about the anus, coming on mainly in the evening; it is often intolerable, especially if they have migrated into the vulva or urethra. Children affected with them are said also to suffer from itching at the nose; and many of the functional disturbances which have been attributed to the presence of more formidable parasites have also been attributed to them. The diagnosis of thread worms can easily be verified by their discovery and that of their ova in the fæces.

*Treatment.*—Local measures are usually amply sufficient for getting rid of thread-worms. The injection of a strong infusion of green tea, quassia, or any other bitter, or of a solution of perchloride of iron or salt, repeated if need be from time to time, is usually efficacious; the use of mercurial ointments or other parasiticide applications in and around the anus may be serviceable for the destruction of the ova in these situations; in addition to which measures occasional purgatives may be administered, and the patient put under a course of tonics.

### 4. *Whip-worm (Trichocephalus Dispar)*

This is said to be not uncommon. But it is rarely met with in this country. It is especially characterised by having a comparatively thick cylindrical body, terminating anteriorly in a delicate filiform process, which forms about two-thirds of the entire length of the parasite. The

FIG. 66. THREAD-WORM.

a. Female and b. Male  $\times 10$ . c. Actual length of female. d. Egg  $\times 250$ .

male measures about one and a half inches long and the female about two inches. The latter is very prolific. The eggs are oval, about  $\frac{1}{400}$  inch by  $\frac{1}{1000}$ , pointed at either end, and presenting a firm brownish-yellow shell. The normal habitat of this worm appears to be the cæcum, to which it attaches itself by burying its thread-like neck in the substance of the mucous membrane.

It does not appear to give rise to any symptoms, and indeed, its presence can only be diagnosed by the discovery of ova in the fæces.

No treatment is needed; the measures most likely, however, to be efficacious in effecting its dislodgment are those already discussed in relation to the ascaris.

FIG. 67.—TRICHOCEPHALUS DISPAR.

a. Female, b. Male (Nat. size). c. Egg  $\times 250$ .

### 5. *Dochmius Duodenalis* (*Sclerostoma Duodenale*)

The *dochmius duodenalis* occurs mainly in hot countries. It is especially prevalent in Brazil and in Egypt, where it causes the so-called 'Egyptian chlorosis,' and is not uncommon in Italy. It was unknown in Switzerland until, during the progress of the works connected with the St. Gothard Tunnel, it was discovered to be the cause of a serious and fatal form of anæmia which largely prevailed among the labourers. It thus acquired a new and special interest in the eyes of Europeans.

The *dochmius* is cylindrical in form, and measures when full-grown about four-tenths of an inch in length. The males and females are equal in this respect; but the former are much more slender than their companions, and may be additionally distinguished, even with the naked eye, by the corolla-like expansion of the caudal extremity, whence (under the microscope) the hair-like double penis may sometimes be seen projecting. The oral orifice, which is turned towards the dorsal surface, is large, strong, somewhat quadrilateral in shape, and armed with eight teeth. The females are very prolific; and the eggs, which are only hatched after their escape from the bowels, are oval,  $\frac{1}{54}$  by  $\frac{1}{1000}$  inch in measurement, and not altogether unlike those of the thread-worm, excepting that they are symmetrical, and that at the time of their discharge they do not contain manifest embryos.

The worms attach themselves firmly by the mouth to the mucous membrane of the duodenum and upper part of the jejunum; so firmly, indeed, that in endeavouring to detach them the mouth may easily be torn off and left behind. They wound the surface deeply, suck the blood

FIG. 68.—DOCHMIUS DUODENALIS.

a. Female. b. Male  $\times 10$ . c. Actual length.

(on which they live) like leeches, cause submucous ecchymoses, and also more or less abundant hemorrhage into the bowels. The numbers present at any one time vary from many hundreds downwards. Dr. Taroni, of Varese, counted as many as 1,250 specimens in the evacuations of a single patient, after the administration of the ethereal extract of male fern.

The *symptoms* due to these parasites are mainly progressive anæmia and debility, which may continue for years, and often sooner or later terminate in death. The severity and danger of the symptoms depend of course on the number of worms present, and, it may be added, on the frequency with which they are recruited. The nature of the patient's illness may be readily determined by examination of the fæces.

*Treatment.*—Since the disease is propagated mainly, if not solely, by drinking water in which the ova or embryos of the parasite are contained, it is especially important, in all places where it is known to prevail, to have special regard to the purity of the water drunk, and as a general rule to have it well filtered or boiled before drinking. For the expulsion of the worms, various vermifuge remedies have been employed. The oil of male fern appears to have been specially serviceable in this respect.

#### 6. *Trichina Spiralis*. *Trichinosis*

The *trichina spiralis* was known only as an occasional inhabitant of the muscular tissue, and regarded as a mere pathological curiosity, until the year 1860; when a case that came under the observation of Dr. Zenker, of Dresden, conclusively showed that, however harmless the encysted parasite might be, the gravest symptoms, and even death itself, might be caused, after its reception into the bowels, during the processes of reproduction which ensued there, and of migration of the young animals into the voluntary muscles. Since that period the 'trichina disease' or *trichinosis* has been fully recognised and frequently observed.

The *trichina spiralis* is met with in the muscular tissue in the form of a minute worm, measuring about  $\frac{1}{35}$  inch in length. Its anterior extremity is somewhat pointed, its posterior thick and rounded; it presents immature sexual organs, and lies coiled up in the interior of an oval cyst. This cyst, which is no essential part of the parasite, but forms around it after it has taken up its quarters, measures about  $\frac{1}{70}$  inch in length, is thick-walled, laminated, transparent and generally studded externally, especially about the poles, with granular calcareous matter. The *trichina*-cysts occupy the striped muscles of the body, and are often especially abundant in those of the larynx. The heart,

FIG. 69.—*TRICHINA SPIRALIS* × 100. Encysted *Trichina* × 100.

however, is rarely if ever involved. They appear in the muscles as minute white grains, distinctly visible to the naked eye, of which the long diameter corresponds to the direction of the fibres. Their apparent size is usually increased by the fact of the development of groups of fat-cells in relation with either extremity. The numbers present vary, of course, in different cases. In a cat experimented upon by Leuckart each ounce of muscle was calculated to contain 325,000 trichinæ; and on the basis of this calculation Dr. Cobbold estimates that a man of medium bulk may easily harbour 20,000,000. He could probably hold many more without much inconvenience. The length of time during which these larval trichinæ retain their vitality is very uncertain. There is no doubt, however, that they may live in the muscular tissue for many years, and that they retain life after the death of their host, and even after the putrefaction and disintegration of his tissues. They do, however, perish *in situ* sooner or later, and then usually undergo calcareous changes. Trichinæ have been discovered in the flesh of various animals besides man, but mainly in that of the pig: and indeed it is from the use of trichinous pork that man becomes affected. The trichina-capsules swallowed with the flesh are dissolved by the gastric juice, and the contained parasites are set free. These then undergo rapid development and attain sexual maturity—the female ultimately acquiring a length of  $\frac{1}{8}$  inch, the male a length of not more than  $\frac{1}{16}$  inch. The ova are hatched within the uterus; and the living embryos, escaping thence into the intestinal canal of the host, at once commence active migration. They attach themselves to the mucous membrane, eat their way through the intestinal walls, and either continue to burrow through all the tissues which lie between them and their destination, or, what is more probable, find their way into the small vessels and lymphatics of the bowels, and are thence conveyed all over the organism. They have been found during this period in almost all parts of the body—in the intestinal walls, abdominal cavity, mesentery and mesenteric glands, connective tissue, and in an as yet unencapsuled condition in the muscular tissue itself.

The progress of events above described is very rapid. The immature trichinæ taken into the stomach become mature on the second day; on the sixth and following days, up to the end of the second or even third week, the embryos are born and commence operations; they probably reach their destination in the course of a week or two, and by the end of a month or a little more have come to the conclusion of their labours.

*Symptoms and progress.*—The symptoms which attend the development and migration of trichinæ are on the whole very remarkable and suggestive of the disease. They comprise, in the first instance, those of gastro-intestinal disturbance; in the next those of general muscular inflammation; and, associated with these, febrile phenomena.

Within a day or two, or at most a week, after the ingestion of trichinous flesh, symptoms not unlike those of enteric fever manifest themselves. The patient suffers from thirst and loss of appetite, with perhaps nausea and sickness; and from colicky pains in the abdomen, with con-

stipation or irregularity of the bowels, or actual diarrhoea. His tongue is coated; and there is more or less mental and muscular prostration, with elevation of temperature, and acceleration of the heart's action. These symptoms, which are ill-defined in the beginning, become aggravated day by day during the first week or ten days of the patient's illness, and in some cases culminate in those of fatal enteritis or peritonitis. More commonly, however, about the end of this time they undergo some remission and then gradually subside. But while they are in progress, and even, it may be, in progress of amendment, other symptoms due to the migration of the parasites develop themselves and soon overshadow them. These consist mainly in gradually increasing pain and tenderness, swelling and stiffness of the voluntary muscles, together with œdema of the subcutaneous connective tissue, copious perspirations, and aggravation of debility and febrile disturbance. The pains have some resemblance to those of rheumatism, but they occupy the fleshy parts of the limbs and trunk and not the joints. The general stiffness, tenderness, and swelling lead to flexion and immobility of the limbs, and it may be to impediment to the due action of the muscles of the tongue and larynx and of those concerned in respiration. Dropsy, which is one of the earliest indications of the migration of the parasites, commences in the face, particularly in the eyelids, then attacks the extremities, and subsequently probably becomes general, involving even the serous cavities. Hoarseness, or loss of voice, and dyspnoea are not uncommon. The temperature presents great differences. In some cases it rarely, if ever, rises above the normal. In severe cases, however, it may reach  $104^{\circ}$ ,  $105^{\circ}$ , or even  $106^{\circ}$ , but then varies greatly and irregularly from day to day, and always presents considerable morning remissions.

The total duration of the disease varies. In mild cases the patient recovers in the course of a month; in many cases recovery is delayed to the end of six weeks or two months; and occasionally the patient continues ill for three or even four months. The trichinous disease varies greatly in severity—its severity depending mainly on the number of living parasites which the patient receives into his bowels. In some instances there are few or no symptoms to attract attention; in some outbreaks, where many persons have been attacked, the mortality has been very light; while in others the death-rate has been twenty or twenty-five per cent. Death may result from enteritis, peritonitis, or pneumonia, or from the debility which the progress of the disease gradually induces; and may occur at any time between the fifth or sixth day and the end of the sixth week.

The presence of trichinosis in its acute stage may possibly be confirmed by the discovery of parasites in the intestinal discharges, or by the extraction by means of a suitable instrument (harpoon) of fragments of striped muscular tissue. The under part of the tongue has been specially recommended for exploration. No symptoms attend the presence of the encapsuled parasites in the muscles. The diseases with which trichinosis is most liable to be confounded are enteric fever, acute tuberculosis, and acute rheumatism; but the distinctions between it and them are obvious.

*Treatment.*—We have not, so far as is known, any power to destroy trichinæ, whether in the intestines or in the substance of the living frame. It is of course possible that remedies useful against other intestinal parasites may be useful against these, supposing their presence to be detected sufficiently early to justify us in attempting to dislodge them. As a general rule, therefore, we can only treat trichinosis on the same principles as we treat other affections made up of local inflammatory conditions and general fever. But we can also employ prophylactic measures; and these are, fortunately, sufficiently simple. They consist in the avoidance of pork which presents the characteristic appearances of the disease, and especially of pork which is not well and completely cooked. The mere toasting to which ham and bacon are frequently subjected is insufficient to destroy the vitality of the trichina. Smoked ham and German sausages are, unless they have been cooked, sources of considerable danger. It is mainly in Germany, where pork, raw, smoke-dried, or imperfectly cooked, is a common article of diet, that trichinosis is known to occur.

#### 7. *Filaria Sanguinis Hominis*<sup>1</sup>

In the year 1870, Dr. Lewis, of Calcutta, observed that certain minute nematoid worms were constantly present in the urine of persons suffering from chyluria; and two years later he published a short monograph, in which, whilst confirming his former statements, he showed that the blood of chyluric patients contained the same parasite in more or less abundance. Later, namely in 1875, he wrote a paper demonstrating the presence of the same animal in the blood and diseased tissues of persons suffering from that form of spurious elephantiasis of the scrotum, labia, and legs which we have already described under the name of elephantiasis lymphangiectodes. This parasite, to which he gave the name of '*filaria sanguinis hominis*,' measures on the average  $\frac{1}{3500}$  inch in diameter and  $\frac{1}{75}$  inch in length; has a rounded anterior extremity, a pointed tail, a definite structureless envelope, with

FIG. 70.—*FILARIA SANGUINIS HOMINIS*  $\times 250$  (after Dr. Lewis).

slightly granular contents, and no sexual organs. The total absence of these organs showed of course that the filariæ were immature; and it was important therefore to endeavour to ascertain the character and habitat of the parent worms, and the source of infection.

Filariæ much like the above have been many times observed in the blood of the lower animals, more especially dogs, in France, China, and America. In such cases both MM. Grube and Delafond and Professor Leidy have discovered in

<sup>1</sup> Dr. T. R. Lewis, *On a Hæmatozoon inhabiting Human Blood: its Relation to Chyluria and other Diseases*, Calcutta, 1872; *The Indian Annals of Medical Science*, No. xxxiv. July 1875; and *The Lancet*, vol. ii. 1877; also Dr. Cobbold, *The Lancet*, vol. ii. 1877.

the right ventricle of the heart mature worms varying from 5 to 7 inches in length, with a diameter ranging from  $\frac{1}{25}$  to  $\frac{1}{16}$  inch; and in the last of Dr. Lewis's papers above referred to he gives an account of a series of original investigations with regard to the prevalence of a similar parasitic disease in the pariah dogs of India. He shows that a considerable number of them present in their blood hæmatozoa which are identical in appearance with those found in man; excepting that they are a little smaller, and do not appear to possess the same distinct structureless envelope. And on dissection he found: 1st, that along both the œsophagus and the thoracic aorta were firm fibrous-looking tumours, varying from the size of a pea to that of a walnut, within each one of which were from one to six worms of a pinkish tinge—the males varying between one and two inches in length, and between  $\frac{1}{30}$  and  $\frac{1}{16}$  inch in diameter, the females measuring from 2 to  $3\frac{1}{2}$  inches long, and from  $\frac{1}{30}$  to  $\frac{1}{25}$  inch thick; and 2nd, that also studding the aorta were nodules, from the size of a millet-seed to that of a pea, containing immature but growing worms from  $\frac{1}{10}$  inch in length upwards, and scar-like depressions, due to either the death of the parasite or its migration and to consequent retrogressive changes.

Since the above observations were made, Dr. Bancroft, of Queensland, late in 1876 and early in 1877, discovered, almost by accident, first in a lymphatic abscess in the arm and next in a hydrocele of the cord, mature female filariæ in length, appearance, and structure not unlike those found by Dr. Lewis in the pariah dog, but apparently a good deal thinner. A little later (August 1877) Dr. Lewis found in dissecting a 'nævroid' scrotal tumour removed from a patient whose blood contained filariæ two mature specimens of the worm. With these were found ova, thin-walled, oval in form, and measuring from  $\frac{1}{1600}$  to  $\frac{1}{1000}$  inch in the long diameter. In this as well as in former dissections numerous embryos were discovered in the diseased tissues. He has also found them in great abundance in the renal arteries and veins and in the substance of the kidneys.

A very interesting paper upon the filaria, from the pen of Dr. Manson, was read before the Pathological Society in December 1880; wherein he reviews the observations in regard to the worm published by previous observers, and supplements them by an account of his own investigations. The following is a brief statement of his more important facts and inferences.

Many of the lower animals are largely affected by different species of filariæ; and in many parts of the world, but more especially in tropical and subtropical regions, human beings are in large proportion infested by the *filaria sanguinis hominis*. The adult filariæ, for the most part, take up their abode in the lym-

FIG. 71.—a. Female  
Filaria (Nat.  
size) (Cobbold).  
b. Ovum  $\times 250$   
(Cobbold).

phatic vessels, wherein, if nothing occurs to disturb or injure them, they live and procreate for many years. They are naturally viviparous, and discharge their young in large numbers into the lymphatic vessels. The embryos not being thicker than blood-corpuscles, and being very active in their movements, readily pass along these vessels, and through successive lymphatic glands, into the thoracic duct, and thence into the blood, with which they are distributed all over the body. But occasionally they abort, and unhatched ova are discharged, which, being several times as thick as the embryos, are unable to pass through the narrow channels of the lymphatic glands, and so (constituting emboli) block them up. This abortion, when once it has occurred, is apt to occur frequently, and thus tends, sooner or later, to cause more or less serious and widespread obstruction of lymphatics. Generally in the lower animals, and to a considerable extent in man, the presence of filariæ causes no symptoms whatever, or at most occasional slight attacks of febrile disturbance; and persons may harbour them for many years, or for life, without any suspicion of the fact ever being excited. In some cases, however, the distinctive symptoms of filarial disease arise: being determined by the fact that groups of lymphatics become obstructed, either as Dr. Manson thinks by embolic ova, or by inflammatory or other changes caused by the parasites. Then lymphatic oedema with dilatation of the distal lymphatic vessels and spaces and overgrowth of connective tissue ensues; and consequently, according to the region involved, we get elephantiasis or lymph-scrotum, or the condition of the kidney or bladder which causes chyluria.

In the great majority of cases the lymph which escapes from the diseased tissues, and that which is mingled with the urine, contain embryo filariæ in greater or less abundance, and occasionally also ova. As regards the relation of the young filariæ to the blood, it is a remarkable fact that it is an almost invariable rule that they are totally absent during the day; that they begin to make their appearance at six or seven o'clock in the evening; that they then rapidly increase in numbers until they attain their maximum; and that they generally disappear about eight or nine o'clock in the morning. Where they hide during the day, or what becomes of them then, is unknown. They never, however, in the blood undergo any further development.

This nocturnal habit of the embryo filariæ led Dr. Manson to suspect that there is some relation between this and their further development; that, inasmuch as they are incapable of such development within their host, and there is no mode beyond the fitful and uncertain one of disease by which they can escape unaided, their normal removal from the body for the purposes of sexual development might be effected through the agency of some nocturnal blood-sucking insect. On investigating the subject he found that, at any rate where he conducted his inquiries, it is due to the operations of a particular form of mosquito. He was able to trace the transference of the embryo filariæ, with the blood in which they were contained, to the stomach of this insect, and also to observe certain developmental changes taking place in them during their

sojourn there. Beyond that he was unable to go. There is little doubt, however, that sooner or later the parasite, thus prepared, finds its way, directly or indirectly, and through the medium of drinking water, into the stomach of its future host, which it pierces, and then proceeds upon its rambles until it finds a suitable residence.

There are many reasons for believing that chyluria and lymphangiectodes, originating in this country, and in temperate climates, are independent of parasitic disease. No doubt our present knowledge of the subject is insufficient to justify us in asserting that this is the case; but it may be observed that any affection causing obstruction of lymphatics is likely to be followed by pathological changes and symptoms resembling those due to the obstruction of these vessels by parasitic influence.

### XIII. VEGETABLE PARASITIC AFFECTIONS

#### A. *Actinomyces*

*History and morbid anatomy.*—Under the above name has been described a progressive inflammatory affection caused by a definite micro-organism, and occurring both in man and in the lower animals. The first case observed in the human being seems to have been one recorded by Langenbeck in 1845. In 1877 Bollinger published his researches on the disease in cattle; in 1878 Israel discovered a similar disease in man; and in 1879 Ponfick, who insisted on the identity between these affections, described another case of *actinomyces hominis*. Since then many cases have been met with, of which a summary is given in Israel's monograph.<sup>1</sup> The earliest case observed in England was recorded in 1885 by Drs. Acland and Sharkey; and shortly afterwards two specimens of actinomyces of the liver were discovered by Mr. Shattock in the museum of St. Thomas's Hospital.

FIG. 72.—ACTINOMYCES (from a case of disease in man) (Payne).

Almost all parts of the body seem liable to attack. Israel divides his cases into three groups, according as the micro-organism is supposed to gain entrance into the system by the mouth and pharynx, the air-passages, or the alimentary canal. In the first case the head and neck suffer; in the second, the thoracic viscera; and in the last, the abdominal organs.

<sup>1</sup> *Kl. Beiträge zur Kenntniss der Actinomykose der Menschen.* Berlin, 1885.

The jaws, vertebræ, and other bones are in some cases the parts chiefly involved.

The morbid appearances vary somewhat according to the stage of the disease and the structures affected by it. But for the most part they comprise tracts of suppurating tissue and sinuses extending from them, and have been largely mistaken for simple or tubercular abscesses. The diseased tracts vary in size, the sectional surface sometimes extending over several square inches; they are generally well-defined, and when occupying solid organs more or less rounded in form; they consist mainly of somewhat dense adventitious fibroid tissue, honeycombed with cavities containing pus or other inflammatory matter. The cavities are for the most part small and close set; but from breaking down of the partitions originally separating them neighbouring cavities may coalesce, and abscesses of considerable size result. The specific element of the disease consists in small, round, sulphur-yellow masses, the largest, perhaps, having the size of a small pin's-head, which, surrounded by inflammatory corpuscles and epithelium-like cells, lie in the small cavities which stud the diseased tissues. They have a roughish granular surface, which under the microscope presents a kind of tessellated character. Each mass is a mulberry-like group of rosettes of delicate club-shaped transparent fibres, radiating from the centre, and occasionally dividing dichotomously in their course to the surface, which is formed by the juxtaposition of their clubbed extremities. In the cases which have been met with at St. Thomas's the microscopic characters present some important differences from those which have just been described, and seem to indicate a different though probably allied micro-organism. There are no club-shaped rods, but the yellow botryoidal masses are made up of extremely delicate threads, some single, some branched, springing from groups of necrosed cells in the centre and at the periphery often prolonged into the inflammatory matter in which the masses lie imbedded. The nature of the actinomyces or ray-fungus and its source are both uncertain. There can be no doubt that the disease is infectious; but although both Ponfick and Johnne have given the disease to calves by inoculation, the attempts to impart it have not on the whole proved very successful.

*Symptoms and progress.*—Actinomycosis is chronic in its progress, and almost always ultimately fatal. The general symptoms are such as usually attend tuberculosis, malignant growth, and other chronic destructive diseases—namely, gradual wasting of tissue and loss of strength, with febrile symptoms of a remittent or hectic type. But added to these are the symptoms due to implication of different organs. The symptoms of the disease, therefore, present great variety, and are by no means distinctive. Indeed one can only be sure of its presence by discovering the characteristic fungus in the diseased tissues or in the discharges from them. In cattle actinomycosis usually commences in the lower jaw, but may affect the tongue and gums, and thence spreads to other parts. It forms in these situations small, slowly-growing, hard tumours, which after a time suppurate and form sinuses, and tend to spread by the development of secondary

similar tumours in the neighbourhood. In man it is supposed, when it affects the gums or their vicinity, to take its starting-point from carious teeth. In some instances the vertebræ are the seat of disease, and the symptoms are undistinguishable from those of ordinary scrofulous caries. When the lungs are affected the symptoms are much like those of chronic phthisis. It is noteworthy, however, that the lower parts of these organs seem to be the main seat of disease. When the liver is attacked, as in the cases met with at St. Thomas's Hospital, the symptoms closely resemble those of hepatic abscess. Actinomycosis of any one of the thoracic or abdominal viscera is liable to be followed, by inflammation of the serous membrane over it; by extension, either by continuity or by dissemination, to other organs; and possibly sooner or later by involvement of the subcutaneous connective tissue, with the development of nodules or tracts of associated suppuration and induration, which finally reach the surface, and then lead to ulceration and the production of sinuses from which thin puriform fluid with fragments of the fungus continues to escape.

*Treatment.*—The indications for treatment are to remove if possible the primary growth by surgical means; or, if this be not feasible, to afford free drainage to any collections of pus which are within reach; and to maintain the general health by tonics, good diet, and all other available measures.

#### B. *Mycetoma* (*Fungus Disease of India. Madura Foot*)

*History and morbid anatomy.*—There is, as it seems to us, a striking resemblance between actinomycosis and mycetoma; and for this reason we here append a short account of the latter disease. The fungus disease has been recognised for many years, but it is to Dr. Vandyke Carter that we are mainly indebted for our present knowledge of its pathology and clinical history. The disease, so far as is known, is peculiar to the natives of India, and attacks only the hand or foot, usually the foot. The affected part becomes swollen and distorted and studded with ulcerated openings, which yield a more or less offensive discharge. The appearances are such as might result from caries or scrofulous disease of the bones. On section the affected tissues are found to be permeated with a network of sinuses, communicating on the one hand with the ulcerated openings, and on the other with cavities of various sizes, either in the situation of the bones, and due to their disintegration and disappearance, or in the substance of the connective tissue and fat. The distinctive feature of the disease, however, is the presence in these cavities and in the sinuses of solid rounded bodies, which also escape with the discharges, and are either of a pale yellow colour or dark brown and almost black. These two varieties of bodies correspond to two distinct varieties of the disease. In the dark form the characteristic masses are firm in consistence, tuberculated on the surface, radiated in texture, vary in size from small grain-like bodies to that of a filbert or even a small orange, and present an almost exact resemblance to truffles. They are made up of abundant thick-walled pigmented mycelial threads, and of capsules

which are probably concerned in the production of spores. In the pale variety, the grains, which have a great resemblance to fish-roe, are of the average size of a millet-seed, are rounded or botryoidal in form, and present a radiating arrangement much like that observed in the dark truffle-like bodies ; but no vegetable fungus has yet been detected in them. It is impossible, however, to help suspecting that the two forms of fungus disease resemble one another not only in their anatomical characters and in their clinical history, but in their etiology, and that further investigation will show that the pale grains, like the dark masses, are mainly vegetable products. The fungus which constitutes the truffle-like bodies, and has been named the *chioniphe Carteri*, is much larger and coarser than the *actinomyces*.

The *symptoms and progress* of mycetoma much resemble those of scrofulous disease of the bones of the foot or hand. The disease begins insidiously and progresses slowly, and can only be surely recognised when sinuses have opened externally, and the characteristic pale or dark bodies are found in the discharges. It may continue for many years, but never ends in recovery.

The only remedy is amputation of the diseased member.

---

#### XIV. DEGENERATIVE AFFECTIONS OF THE STOMACH AND BOWELS

Degenerative changes of the mucous membrane play, no doubt, an important part in the various chronic disturbances of the stomach and bowels, to which the terms dyspepsia, diarrhœa, and the like are usually applied. They follow upon chronic inflammation and other persistent lesions of the alimentary mucous membrane, and occasionally depend on the presence of certain forms of cachexiæ. They comprise mainly : fatty degeneration and wasting of the glands, associated either with general atrophy of the mucous membrane or with increased development of fibroid tissue ; and lardaceous change. Lardaceous degeneration affects the small intestine much more frequently than the stomach or the larger bowel, and probably never occurs except in association with advanced lardaceous disease of the liver, spleen, or kidneys. The villi chiefly suffer.

The symptoms referrible to the different kinds of degeneration do not at present admit of identification.

---

#### XV. OBSTRUCTION OF THE STOMACH

*Causation and morbid anatomy.*—Many of the morbid conditions which have already been described involve more or less serious impediment to the due performance of the mechanical functions of the stomach,

and consequently to the due transmission of its contents onwards; and indeed the symptoms arising from obstruction form an important part of their clinical history.

Obstruction occurs chiefly at the pyloric and cardiac orifices; it may, however, arise in some intermediate part. It may be due to mere fibroid thickening or cirrhosis; to malignant disease; to the cicatrization of large ulcers; to the pressure of external tumours; to accumulation of hair, cocoa-nut fibres, or other solid matters which have from time to time been swallowed; to paralysis or spasm.

The consequences of obstruction at the cardiac orifice have already been considered under the head of œsophageal disease; they are dilatation and hypertrophy of the œsophagus, and contraction and atrophy of the stomach. In pyloric obstruction the food which is received into the stomach tends to accumulate within it, and thus to involve its dilatation and hypertrophy. The dilatation under such circumstances is sometimes enormous. If the impediment occupy some intermediate position, its influence over the form and functions of the stomach will, according to circumstances, approximate either to that of cardiac or to that of pyloric obstruction. In some cases habitual starvation causes more or less permanent general contraction of the stomach; in some cases habitual over-eating or accidental or ill-understood conditions involve extreme dilatation of the organ, and occasionally such dilatation is very rapidly developed, and acute in its progress. Both of these states are apt to be attended with many of the phenomena of pyloric stricture.

*Symptoms and progress.*—The symptoms of cardiac obstruction are, mainly, ability to perform the act of deglutition, and in succession to this act uneasiness, referrible to the situation of the cardiac orifice, and the rejection of the matters swallowed by a process which generally has more resemblance to eructation than to vomiting. The patient probably has a good appetite, but cannot gratify it, and suffers from all the usual symptoms of starvation. In most cases the obstruction is partial only, and more or less food finds its way into the stomach. In some the retention of food in the dilated œsophagus lasts for a considerable time, and the retained matters prior to their rejection undergo putrefaction or fermentation, and become mixed with mucus secreted from the surface of the tube. The epigastric region shrinks and becomes concave, owing to the necessary contraction of the starved stomach.

The symptoms referrible to obstructive disease of the pylorus are, in many important respects, different from the above. The patient can swallow with ease, and anything that is swallowed finds its way without difficulty into the stomach; whence (according to the degree of impediment present) it is in part transmitted more or less slowly onwards, in part, after a while (it may be half an hour, an hour, several hours, occasionally even several days), and after having caused more or less gastric uneasiness, rejected by vomiting. The characters of the vomited matters depend largely upon the length of time they have been retained. If they be discharged shortly after ingestion, they consist mainly of

partially digested food mingled with the normal secretions of the stomach; if after a long interval they have generally undergone putrefactive or

FIG. 73.—SARCINA VENTRICULI  
× 500.

fermentative changes, are fetid, abnormally acid, and probably contain sarcinæ or the yeast-fungus, or both. Their quantity varies considerably, and sometimes amounts to several pints. The appetite is more likely to suffer in pyloric than in cardiac obstruction, but is not unfrequently retained. The dilatation of stomach which attends this affection reveals itself locally by protrusion of those parts of the abdominal surface with which the organ lies in contact, and probably by displacement of the diaphragm upwards. If it

be moderate, it causes fulness of the epigastric region only; if it be considerable, the body of the organ descends, forming a loop between the pyloric and cardiac orifices, and the chief distension then probably occupies the umbilical and hypochondriac regions—the epigastrium presenting a comparative depression. In some cases the dilated stomach occupies nearly the whole of the anterior part of the abdomen, and it may reach the pubes. That the distension is due to the stomach is shown: partly by its situation; partly (if it be considerable) by its looped form; partly by observing the peristaltic movements, which are generally easy of recognition and admit of being readily excited; and partly by the evidences which palpation and percussion give of a large cavity containing air and fluid.

The symptoms due to general contraction of the stomach are especially: inability to take food, excepting in small quantities; irritability of the organ; and tendency to vomit shortly after the ingestion of food. Simple dilatation of the stomach differs little, if at all, in its symptoms from incomplete pyloric obstruction.

FIG. 74.—YEAST-FUNGUS × 500.

In all of the above cases, starvation, emaciation, asthenia, and the phenomena which attend these conditions, supervene with more or less rapidity. Further, various complications are apt to arise in their course and to prove fatal, among which may be mentioned gastritis and peritonitis.

*Treatment.*—The treatment of obstruction must vary somewhat in different cases, in dependence partly on the site of obstruction, partly on its cause. If it be at the cardiac orifice, the careful passage of bougies may serve to maintain an available passage; and, failing this, the question of making an opening into the stomach at the epigastrium, and of feeding the patient through this opening, may be entertained. If it be at the

pyloric orifice, or if the case be one of simple dilatation, it may become necessary under certain circumstances, casually or periodically, to empty the distended organ by means of the stomach-pump or an elastic tube, and even to wash it out with antiseptic solutions, or to let off some of the gaseous accumulation by acupuncture through the abdominal walls. In all cases it is important to give food in small quantities at a time, and in the fluid or semi-fluid condition, in which form it most readily passes through a narrowed or strictured orifice. In cases of pyloric disease or passive dilatation, it is further important: that the stomach be not overburdened with food, and hence that this be administered in a concentrated form; that putrefaction and fermentation be obviated by the use of appropriate remedies, such as creasote, the hyposulphites, or thymol; and that tendency to vomit and gastric uneasiness be met by the measures elsewhere recommended for these purposes. Lastly, it is often necessary to feed the patient per rectum.

For an adult, it is not generally expedient to administer thus more than 3 or 4 ounces at a time, or to repeat the operation oftener than twice or thrice in the twenty-four hours. If for any reason it is deemed advisable to use a larger quantity, say half a pint or more, it is probably best, in order to ensure its retention, to follow the practice adopted by Dr. Newington, of first injecting the fluid high up into the rectum, and next plugging the bowel with a moist sponge the size of the fist passed above the internal sphincter, and attached to a string or tape by which it may be withdrawn.

## XVI. OBSTRUCTION OF THE BOWELS

The affections which are here to be treated of present many features in common with enteritis, and their description is not unfrequently included in the description of that disease. Enteritis does indeed occur at some period or other in the course of most of them; but their special claim to form a group apart consists in the fact of the existence in all of them of some mechanical impediment to the transmission of the contents of the bowels, in connection with which enteritis is apt to supervene. They are: stricture, compression and traction, twisting, internal strangulation, impaction of foreign bodies, and intussusception. It will be convenient to preface our observations under these heads with some remarks upon their common factor, constipation.

### A. Constipation

*Causation, morbid anatomy, and symptoms.*—It may doubtless be accepted as a general rule that persons enjoying robust health, and undisturbed in the due performance of their various functions, have an alvine evacuation at least once daily. Yet many, who at any rate seem equally healthy, have their bowels habitually relieved every two or three days only, or even but once a week or fortnight. Cases are not altogether

rare in which some degree of good health has been maintained for many years, although fæcal evacuations have during that time occurred only at intervals of six weeks or two months. Cases, indeed, are on record in which the interval between successive evacuations has been extended to a period of three months. In most cases, however, retention beyond the usual period is apt to produce not only local uneasiness, such as fulness, heat, tendency to piles, and flatulence, but also some degree of general disturbance, indicated by headache, foul breath, loss of appetite, and dyspeptic symptoms, and not unfrequently ends with the occurrence of tenesmus and even slight dysenteric diarrhœa. Habitual constipation is usually attended with chronic discomforts of the same kind; but it leads also to more or less permanent hypertrophy and dilatation of the rectum—conditions which render this tube less efficient for the performance of its expulsive duties. When constipation is of long duration, not only the rectum but the whole of the large intestine may become dilated by its contents and hypertrophied, the mucous surface may be fretted into ulcers, and perforation may ensue. The dilatation is sometimes so great that the colon measures from ten to twelve inches in circumference. The chief dilatation occurs in the rectum, sigmoid flexure, and cæcum. The hypertrophy under such circumstances is general, but it is usually greatest in the sigmoid flexure and upper part of the rectum, where the thickness of the muscular coat may be  $\frac{1}{8}$  inch or more.

Constipation depends on various causes. It sometimes arises temporarily from change of diet, scene, or habits, among which may be included anything interfering with the regular performance of defæcation; it is common in many diseases; and it occurs in a chronic form in chlorotic or dyspeptic girls and young women, and in persons of sedentary habits or sluggish constitution. Among local conditions which may be supposed to operate in a greater or less degree in the above cases are: first, modifications in the character of the fæces, such as we see in diabetes, where they become preternaturally dry and proportionately diminished in bulk; second, sluggishness or debility on the part of the rectum itself; and, third, affections at or in the neighbourhood of the anus, rendering defæcation painful.

### B. Stricture

*Causation and morbid anatomy.*—By this term is meant a circumscribed diminution of the calibre of the bowel. Stricture is sometimes due to spasm; but although spasm undoubtedly forms a very important element in many cases of intestinal obstruction, it is rare as an independent affection, and in this form is practically limited to the rectum and anus. Indeed, spasmodic obstruction, even in these situations, is probably always secondary to ulceration, excoriation, or morbid sensitiveness of the mucous membrane. Stricture, in the vast majority of cases, is the consequence of some organic change—cicatrization after ulcer, cirrhosis, or some adventitious growth (malignant or other) occupying the intestinal walls. It rarely follows ulceration, unless this be of large extent, or en-

circle the bowel. It seldom, if ever, ensues on the cicatrisation of typhoid ulcers, and not very often on the healing of tubercular ulcers. It is a much more common consequence of dysenteric or syphilitic ulceration and of the separation of a portion of bowel in intussusception. But most frequently the ulcer to which it is traceable has, so far as we know, no specific or ascertainable origin. Cicatricial stricture may form a mere ring or occupy the bowel for several inches of its length. The surface is sometimes completely cicatrised; sometimes presents still unhealed spots of ulceration, with fungus excrescences or granulations; and is often separated from the subjacent muscular coat by a more or less abundant formation of dense fibroid tissue. Stricture again, especially in the lower part of the rectum, is sometimes connected with the progress of chronic inflammatory changes or the overgrowth of fibroid tissue, not only in the walls of the rectum, but also in the surrounding connective tissue of the pelvis. But by far its most frequent cause is the development of carcinoma in the substance of the intestinal walls. When carcinoma causes stricture or serious obstruction, it is for the most part a primary growth at the seat of stricture, and, like simple ulcer, sometimes forms a mere ring round the gut, sometimes involves a comparatively large area. Congenital stricture or occlusion of the bowel is mainly an affection of the anus or rectum, and falls therefore especially under the cognisance of the surgeon. It has, however, been occasionally met with in the duodenum, in the neighbourhood of the orifice of the common bile-duct.

The presence of stricture always leads, in greater or less degree, to certain results. These are: first, undue accumulation of feces in the bowel above, with proportionate dilatation of its tube; second, hypertrophy of the muscular walls of the dilated bowel; and, third, diminution in calibre, and even atrophy, of the bowel below. It is an interesting fact that, in stricture of the colon, the greatest degree of dilatation is often found not in the portion of bowel immediately above the stricture, but in the cæcum. The tighter or longer the stricture, the more marked, other things being equal, will be the several consequences just named; and the more danger will there be of the supervention of permanent obstruction. Yet it is remarkable that tight and long strictures are often found after death in cases in which during life there has been no suspicion of their presence—a statement more particularly true of stricture of the small intestine, in which part the contents are, as a rule, semi-fluid and easy of propulsion; and on the other hand that slight annular strictures of the large intestine are frequently the causes of fatal obstruction. The lodgment of feces above a stricture is apt not only to prevent the complete healing of the ulcer to which originally the stricture may have been due, but also to cause erosion and ulceration in the dilated bowel above, and ultimately perforation.

Stricture may arise anywhere in the bowel, but is met with in different parts with different degrees of frequency. Its occurrence as a fatal disease in the small intestine is rare. It is mainly indeed a disease of the larger bowel. According to Dr. Brinton, out of 100 fatal cases of stricture of the

large intestine, 4 occur in the cæcum, 10 in the ascending colon, 11 in the transverse colon, 14 in the descending colon, 30 in the sigmoid flexure, and 30 in the rectum. It is more frequent in men than in women; and the average age at which it proves fatal is a little over forty-four.

*Symptoms and progress.*—The symptoms due to stricture of the small intestine are rarely sufficiently definite to justify us in diagnosing its presence. They are mainly occasional colic, nausea, and sickness. Even in the case of the large intestine they may for a long time be vague and inconclusive, and indeed misleading. The patient perhaps suffers only from occasional attacks of colicky pain, associated it may be with constipation; but not unfrequently, during the earlier period, diarrhœa is a prominent symptom. If the stricture be in the lower part of the rectum solid motions generally soon assume a narrow tape-like or pipe-like form.

The symptoms of absolute obstruction occasionally come on quite suddenly, but are more frequently preceded by long-continued tendency to constipation. Sometimes also the patient, previous to his final attack, has experienced one or more similar attacks, which have yielded to treatment. The symptoms of impassable stricture are: insuperable constipation; painful peristalsis, coming on periodically, and often rendering itself audible by borborygmi, and visible through the abdominal walls; abdominal distension and uneasiness, followed by nausea, vomiting, and hiccough; and death at last from simple asthenia. The vomited matters become after a while stercoraceous. Febrile symptoms and abdominal tenderness may be absent from first to last; but sometimes inflammation supervenes, or perforation takes place, and then enteritic or peritonitic symptoms become superadded. When the case is free from these or other complications, its progress is essentially chronic, and the patient, if not improperly treated, may live for a considerable time, haply for several weeks.

In determining the seat of stricture, it is well to recollect that at least three-quarters of the strictures of the large intestine are situated to the left of the mesial plane of the body. We need not, however, rest content with a simple calculation of chances. It is natural to believe that the distension of the bowel above the stricture, and its collapse below, should reveal themselves to manual, if not to ocular, examination; and in many cases undoubtedly the form and position of a struggling, or even of a quiescent, length of distended bowel may be thus readily identified. It must not be forgotten, however, that thickness or rigidity of the abdominal walls, tenderness, the presence of tumours and the altered positions which greatly distended tracts of bowel are apt to assume, often prevent the easy recognition of even extreme differences of intestinal dilatation and fulness. Dr. Brinton maintains that the amount of fluid which may with care be injected per anum is a very valuable guide in estimating, so far as the large intestine is concerned, the seat of stricture. This method of investigation is, however, scarcely trustworthy, unless the stricture be at a comparatively small distance from the anus. But when in this latter situation, its presence may often be ascertained by the introduction of the finger, or even of the entire hand; and if it be beyond the reach of actual

touch, yet in the rectum, the careful introduction of a bougie may possibly reveal its position.

### C. *Compression and Traction*

*Causation and morbid anatomy.*—Under these terms we include those cases in which the bowel is obstructed either by pressure exerted on it from without, or by being dragged out of its normal position by adhesions, without being at the same time strangulated.

Here also may be placed those cases in which the rectum is obstructed and defæcation rendered painful or difficult by the pressure of a displaced or enlarged uterus, or of a uterine or ovarian tumour. Any abdominal tumour may, conceivably, have a like effect on some part or other of the alimentary canal; and even the effused blood from a ruptured aneurysm may surround and compress the duodenum or some part of the colon. But the cases here more particularly referred to are those in which obstruction is due to the embarrassment of a greater or less length of bowel, caused by the presence on its outer surface of lymph or false membrane, which binds it to surrounding parts, and sometimes constricts it, sometimes leads to the formation of sharp angular bends. In some of these cases the bowel has been incarcerated in a hernia, and portions of it have become invested in adhesions which attach it to the neck, or some other part of the sac, or to the omentum; in others, the transverse colon or sigmoid flexure, or some other tract of bowel, is hooked down, as it were, by bands of lymph to the uterus, ovary, or some other structure within the pelvis; in others, again, several contiguous coils of small intestine are tightly bound together, forming a kind of tangled mass. This is not unfrequent in the neighbourhood of the cæcum. Fatal cases always furnish distinct evidence, in the contraction and emptiness of the bowel below, and in the fulness, dilatation, and hypertrophy of the bowel above, of more or less complete obstruction. But the part in which actual obstruction has taken place, though contracted and for the most part empty, frequently admits with ease of the passage of the finger, or even of some larger body. The immediate cause of obstruction, indeed, is rarely a simple tight constriction. These lesions are of far more frequent occurrence in the small intestine than in the large, and, as Dr. Fagge points out, may, from the clinical point of view, be regarded as the strictures of the smaller bowel.

*Symptoms and progress.*—The symptoms of these affections are almost, if not quite, identical with those of stricture. It is impossible, indeed, to make any absolute clinical distinction between them. Obstruction of the small intestine, however, is as a rule more early followed by vomiting than obstruction of the large intestine; and it may occasionally be possible, by careful examination of the surface of the abdomen, to ascertain whether abnormal distension is due entirely to dilatation of the smaller bowel, or mainly to distension of the colon. In those cases in which old adhesions have formed around the lower part of the ileum, a tumour may sometimes be felt in the right iliac fossa and in these same cases there

may be (extending over many months or even over many years) progressive dilatation and hypertrophy of the small intestine, and progressive contraction and atrophy of the large intestine, associated with gradually increasing frequency and violence of peristaltic action, colic, nausea, and sickness, the habitual discharge from the bowels of thin, yellow, fetid evacuations, and slowly developed emaciation and debility, terminating at length in death from asthenia.

#### D. *Torsion or Twisting*

*Causation and morbid anatomy.*—Cases are occasionally met with in which after death a loop of bowel is found to be twisted, enormously dilated, and congested, and full of fetid pitchy stuff, consisting partly of faecal matter, partly of the bloody secretion of the affected mucous membrane. The portions of bowel most liable to torsion are the cæcum and sigmoid flexure. The causes of torsion are obscure; but, at any rate, the accident appears to arise suddenly; the affected loop becomes twisted, once or even more than that, upon its axis, and is at once rendered more or less impervious; and, what is still more important, the trunk-vessels which supply it becoming similarly twisted and occluded, congestion, inflammation, gangrene, and paralysis of the bowel necessarily ensue. When the twist is of the sigmoid flexure, the loop of bowel sometimes undergoes such enormous distension as to measure a yard in length, and three or four inches in diameter, and may occupy the whole of the front of the abdomen. The mucous membrane and sub-mucous tissue become thickened and black with congestion and extravasated blood; and the peritoneal aspect acquires a slaty hue, and gets studded with patches and streaks of congestion and inflammatory exudation. The contents have already been described. The bowel below the lesion is usually contracted and empty, while that above it is for the most part dilated, and may present patches of congestion and contain matters which have regurgitated from the diseased tract.

*Symptoms and progress.*—This affection is sudden in its onset, and in most cases rapidly fatal—the patient sometimes dying in the course of a day or two, rarely surviving for a week. The symptoms are in the main those of strangulated hernia. The patient generally suffers at first from severe abdominal pain, attended with constipation, vomiting, and rapid flatulent distension of the belly. And, although febrile phenomena may occur, he very rapidly falls into collapse, with falling temperature, clammy perspiration, feeble and irregular pulse, sighing respiration, great muscular debility and restlessness, and withal more or less drowsiness. Generally the urine is scanty or suppressed; the bowels completely obstructed; and the patient sensible till the last.

It is remarkable that vomiting and hiccough are often absent in a greater or less degree, at any rate are not prominent symptoms; and that, notwithstanding the enormous distension of the abdomen, there is frequently little or no absolute pain, excepting early in the disease, and little or no tenderness. Indeed, the patient often, as in colic, is relieved by

pressure or friction. When the torsion involves the sigmoid flexure, the long tube may easily be introduced into the diseased bowel; and the nature of the case may possibly be diagnosed partly by this fact, partly by withdrawing some of the contents.

### E. *Internal Strangulation*

*Causation and morbid anatomy.*—This arises from similar causes to those which produce ordinary strangulated hernia, namely, constriction or nipping of a portion of bowel by the edges of some natural or artificial orifice through which it protrudes, with consequent arrest of the circulation of blood through it, and impediment to the passage of fecal matters along it. Such orifices are the foramen of Winslow, congenital or acquired perforations in the mesentery, meso-colon, great omentum, or other peritoneal duplicatures, or apertures formed with the aid of neighbouring parts by bands of fibroid tissue extending from one point of the peritoneal surface to another.

Hernial protrusion through the foramen of Winslow is exceedingly rare. Perforation of the various peritoneal duplicatures, with passage of bowel through the perforation, is much more common, and often the result of laceration from violence. This accident is most frequent in connection with the mesentery; but it occurs also in connection with the great omentum, the meso-colon, the fold belonging to the vermiform appendix, the suspensory ligament of the liver, and the broad ligament of the uterus. There is no part of the peritoneal surface to which bands capable of producing strangulation may not be attached; but there are certain structures and certain conditions of parts with which they are specially apt to be connected. Thus the vermiform appendix often adheres to neighbouring structures, such as the mesentery, small intestine, colon, and ovary, forming a kind of loop; diverticula of the ileum become attached, usually by the apex, to the mesentery or some other adjoining part, or are prolonged to the umbilicus by a cord—a remnant of foetal life. Again, such bands are often connected with the mesentery, the parts concerned in old ruptures, or the pelvic organs—more particularly the uterus, Fallopian tubes, and ovaries. It may further be noted that strangulation occasionally results from the slipping of a loop of intestine under the lower edge of the unusually elongated mesentery of a portion of bowel hanging low into the pelvis, or under the pedicle of an ovarian or uterine tumour. Finally, there are rare cases of internal strangulation in which the bowel protrudes into a lacerated bladder, uterus, vagina, or bowel, or through an acquired or congenital communication between the peritoneum on the one hand, and the pericardium or one of the pleuræ on the other.

The small intestine is much more frequently strangulated than the large; and of the large intestine the parts most liable to this accident are those which are most freely movable, especially the sigmoid flexure and the cæcum. Internal strangulation occurs at any age, but generally above thirty. It seems, however, that strangulation from bands connected

with the vermiform appendix and diverticula are most common at a comparatively early age.

The *symptoms* of internal strangulation are identical with those of ordinary strangulated hernia, and so like those which have already been described as the symptoms of torsion and the severer forms of enteritis that there is no need to give any special account of them.

#### F. *Impaction of Foreign Bodies*

*Causation and morbid anatomy.*—The ordinary intestinal contents, no matter how indigestible, unwholesome, or imperfectly comminuted the ingesta from which they are derived may be, very rarely cause by their accumulation permanent intestinal obstruction; yet it is doubtless the fact that undigested masses of food do sometimes in their passage along the small intestine move with difficulty or become temporarily impacted, and so produce pain and sickness and even symptoms of obstruction. Hard foreign bodies of comparatively small size (coins, bits of bone, teeth, marbles, plum-stones, and the like) generally traverse the intestine without causing inconvenience; and occasionally sharp bodies, such as pins, prove equally innocuous. They are all, however, a source of danger, especially in the presence of strictures, above which they are apt to become lodged; or from the fact that they may slip into diverticula or the vermiform appendix, or (if they be hard and pointed) may perforate the intestinal wall, and cause, according to the seat of perforation, fatal peritonitis, circumscribed abscess, or fistula. Further, an accumulation of such bodies, as for example a large number of cherry-stones, may become welded into a mass sufficiently bulky to obstruct fatally a perfectly healthy bowel. Insoluble matters in the form of powders or fibres, when habitually swallowed even in small quantities, often concrete into hard masses. These sometimes are round or oval, and may then be termed intestinal calculi; sometimes form hollow casts of the portion of the gut in which they lie. The former are probably always found in the large intestine; the latter rarely, if ever, occupy any other part than the rectum. Among the substances here referred to are peroxide of iron, carbonate of magnesia, imperfectly cooked starch, and oat-hairs derived from articles of food made from oats. Among cases of exceptional rarity must be named those of persons who have been in the habit of swallowing knives, pins, string, hair, or cocoa-nut fibres. These things are generally found accumulated either in the stomach or in the upper part of the small intestine, and when fibrous usually become felted and form masses which take the shape of the cavities in which they lie. It must not be forgotten also that lumps of indurated fæces occasionally lodge in the cæcum, sigmoid flexure, or some other part of the colon, and remain thus lodged, without causing obstruction, for months together, or even for an indefinite period. Such lumps may be situated above a stricture, or in the pocket of a chronic ileo-cæcal invagination, or may lie passive in a sluggish and dilated bowel as a sequel probably of prolonged or habitual constipation. They may be recognised as fæcal by their position, their mobility and tendency to descend, and

especially by their doughy consistency and freedom from marked tenderness.

But the usual cause of fatal impaction, and that with which we now have more especially to do, is the escape of biliary concretions from the gall-bladder into the small intestine. The concretions here referred to are single stones or masses of coherent stones of considerable bulk, varying at a rough estimate from three to four inches in circumference, and from one inch to two, three, or even four in length. It is obvious that concretions of this magnitude can scarcely escape from the gall-bladder *per vias naturales*; and indeed there is no doubt that their discharge is in all cases effected through an ulcerated opening between the gall-bladder and duodenum. When such a body has got into the duodenum it is carried on with the other contents of the bowel by the ordinary peristaltic movements. But its mere bulk prevents it from moving rapidly; besides which it provokes, by its shape, size, and hardness, irritation if not inflammation in the mucous surface over which it passes, and spasmodic contraction of the muscular walls. It hence continues its progress fitfully onwards, until finally it becomes permanently arrested in the jejunum or ileum. Then all the effects of complete obstruction, conjoined with those of enteritis, supervene: the bowel below becomes empty and shrunken, that above distended and generally more or less inflamed; while at the seat of obstruction and in its immediate neighbourhood the inflammation becomes intense, speedily extends to the peritoneal surface, and not rarely ends in gangrene and perforation. Gall-stones seldom if ever lodge in any part of the large intestine; and when large ones are found there they have probably gained an entrance directly by ulceration between the gall-bladder and transverse colon. Gall-stones are usually a product of the later periods of life; and hence obstruction from them can scarcely be looked for excepting in advanced age. It occurs, indeed, rarely before the age of fifty, and much more frequently in women than in men.

*Symptoms and progress.*—The symptoms due to the impaction of gall-stones are as nearly as possible identical with those of internal strangulation or volvulus. These cases, however, are amongst the gravest in their symptoms, and the most rapid in their course, of all cases of intestinal obstruction. Dr. Brinton calculates their average duration at five days. A clue to the nature of the case may sometimes be furnished by the occurrence of precursory symptoms due to the passage of the calculus along the bowel, and by the detection of the hard mass itself *in transitu*. The age and sex of the patient are also suggestive. There is not necessarily or even generally in these cases any history of hepatic colic or other indication of hepatic affection.

#### G. Intussusception

*Causation and morbid anatomy.*—By this term is meant the slipping of a portion of the bowel into that which immediately succeeds or precedes it and is continuous with it. In almost all cases the bowel above descends into the bowel below. As the result of the latter accident we find the normal

course of the intestine interrupted by a kind of knot, in which three successive lengths of tube lie almost concentrically one within the other—the innermost being the portion of bowel which has descended, the outermost the portion into which the descent has occurred, the middle or intermediate length that which unites the lower extremity of the former with the upper extremity of the latter. The last is of course inverted, and has its mucous aspect facing outwards and in contact with that of the outermost layer. In the descent of the inner two lengths of bowel the mesentery belonging to them is necessarily dragged down with them into the pouch which they form, and by the traction which it exerts tilts the double tube or invaginated portion of bowel so that the lower orifice, instead of lying in the axis of the containing bowel, faces and rests upon some portion of its circumference. The several layers are generally transversely corrugated, and this condition is always most marked in the middle tube. The immediate effects of intussusception are: first, obstruction to the passage of the intestinal contents; and, second, impediment to the circulation of blood through the inner two cylinders of involved bowel, to which the stretched and compressed mesentery belongs. Nevertheless the obstacle which an intussusception opposes is often incomplete; for it is certain that in a good many cases fecal matters pass pretty constantly through it. The obstruction to the circulation soon renders the mucous and muscular coats of the inner two tubes black or nearly so with congestion and effusion of blood; and the serous surface acquires a slate colour. At the same time these parts become much swollen, and sanguinolent serum or blood escapes from the mucous membrane into the interval between the opposed surfaces of the outer two tubes, into the central canal, and into the bowel below the seat of disease. At a somewhat later period coagulable lymph is secreted from the opposed serous surfaces of the middle and internal layers, and these may consequently become agglutinated in their whole length. In most cases an intussusception increases for a time more or less rapidly, owing to the active peristaltic movements of the several segments engaged. This increase is so effected that that portion of the bowel which formed the lowest point of the invaginated mass in the first instance continues to form its lowest point to the end of the chapter; in other words, the middle tube of an intussusception increases in length at its upper end only, and at the expense of the outer tube. The length of bowel engaged in an intussusception varies widely. Including in one measurement the inner two tubes only, it may be said to range usually from two or three inches up to three or four feet. Dr. Peacock records a case in which there were good grounds for believing it to have been no less than twelve feet.

Intussusception may arise at any part of the intestinal canal, but it occurs in different parts with different degrees of frequency. Jejunal and ileal intussusceptions are met with almost exclusively in adults, and form collectively about one-third of the total number of fatal cases. These are usually attended with speedy strangulation of the bowel, and run a rapid and for the most part rapidly fatal course. Ileo-cæcal invagination occurs

largely among young children, including babes of a few months old. According to Dr. Brinton, half the total number of these cases are in children under seven years of age. This is the most common form of the disease, accounting for more than half the total number of deaths. It commences with the descent into the cavity of the cæcum of the lips of the ileo-cæcal orifice, which henceforth form the lower extremity of the invagination. As this increases the descending ileo-cæcal orifice carries down with it more and more of the ileum to form the central tube, and inverts first the cæcum and then a gradually increasing quantity of the colon to form the inverted or middle layer; and, still descending, finally, in some cases, reaches the rectum, or even protrudes from the anus. It is in this variety that the greatest length of bowel may be engaged; in it the transverse folding of the several layers of intestine is usually well shown, especially in the middle tube, which is often also much convoluted and twisted; and in it complete strangulation and complete obstruction to the passage of fæces are comparatively rare. Intussusception commencing in the colon is of somewhat unfrequent occurrence; and still more rare is intussusception of the rectum. The rarest form of all, probably, is that due to the descent of the ileum *through* the ileo-cæcal orifice. Intussusceptions are sometimes multiple; and two or three cases have been recorded in which an ordinary invagination at the ileo-cæcal orifice has been associated with another taking the inverse direction.

If the patient survive sufficiently long, various consequences are apt to ensue. The inflammation, which by its products unites the opposed serous surfaces of the inner two layers, may spread beyond its primary seat, and cause general peritonitis. Or, after these layers have become united, a further descent of bowel may take place into the portion already invaginated. Or the invaginated bowel may by its extremity fret the wall of its containing tube, causing ulceration and perforation. It may even protrude bodily into the peritoneal cavity. But by far the most interesting and important event is the sloughing and separation of the included layers of bowel. This occurs almost exclusively in those cases in which the small intestine is alone engaged, and the strangulation of the contained bowel is most complete. This, first deeply congested, soon becomes gangrenous, and then, after a while, getting detached either bit by bit or in mass, gradually works its way downwards, and is expelled. The separation of the slough generally leaves the upper extremity of the outermost tube firmly united at the neck of the intussusception with the lower extremity of the healthy bowel above. But during the process of separation the adhesions are apt to rupture, and fæcal matter to extravasate into the peritoneal cavity. The discharge of the invaginated bowel usually occurs between the twentieth and thirtieth day; but it may take place as early as the sixth or seventh day, or be delayed for a year or two. The results of separation seem to be favourable in about half the total number of cases. In the remainder death often results sooner or later from stricture.

*Symptoms and progress.*—The occurrence of intussusception is attended with sudden and severe abdominal pain of a gripping or twisting character,

usually referred to the neighbourhood of the umbilicus. This generally ceases in a short time, but after an interval recurs temporarily, and then perhaps continues to recur and remit alternately. There is not necessarily any abdominal tenderness, and indeed the patient frequently finds relief, as in colic, from pressure on the abdominal parietes. Sympathetic vomiting may be an early symptom, but in the beginning is often absent. Constipation usually follows upon the sudden attack of pain; but sometimes there is actual diarrhœa, and generally more or less abundant discharge of blood furnished by the congested bowel. The symptoms which mark the subsequent progress of the case depend partly on the situation of the intussusception, partly on the degree of strangulation.

In ileo-cæcal invagination strangulation is rare, and consequently the case tends to be protracted. In this event the symptoms are apt to be ill-defined; paroxysms of pain are often slight, and recur at distant intervals; constipation may exist at the beginning only, or may recur from time to time, or may never be distinctly present; there is generally vomiting. As the case progresses, however, the pain often increases in severity; the vomiting becomes more or less incessant, and probably stercoraceous; the alvine evacuations either continue to pass or become re-established; blood and mucus are discharged in variable quantities; and even dysenteric diarrhœa may come on. And then, after a longer or shorter period, sometimes two, three, four, or even twelve months, the patient, who has been gradually getting emaciated and feeble, dies of simple exhaustion. This form of the disease, both in its earlier and in its later stages, is apt to be mistaken for dysentery.

When the small intestine is the seat of disease, strangulation usually takes place at once, and its occurrence adds the symptoms of enteritis to those of mere invagination. The case, therefore, speedily assumes a very threatening aspect. Febrile symptoms manifest themselves, the abdomen becomes tender, incessant vomiting comes on, the bowel gets occluded, but at the same time probably blood in some abundance is discharged per anum. With such symptoms the patient, as in simple enteritis or internal strangulation, may speedily succumb; but sometimes at a moment when the disease appears still to be progressing unfavourably, the constipated bowel begins to act, offensive stools, mixed with blood and mucus, begin to be discharged, vomiting diminishes or ceases, febrile phenomena abate, and, after a longer or shorter time of dysenteric symptoms, a sequestrum is voided in the form of a dark fetid mass.

A further indication of the presence of intussusception is the discovery of a tumour. No doubt, this cannot always be detected; but it is most likely to be found in cases of ileo-cæcal or colic invagination. That the tumour is due to intussusception may be gathered: partly from its position; partly from its form; partly from the fact of its gradual enlargement and change of position: but above all from its hardening and enlarging and then subsiding under the influence of peristaltic movements. The tumour arising from ileo-cæcal invagination is generally discovered in the left lumbar and iliac regions. If the tumour descend into the rectum, or

protrude externally, its nature may of course be readily recognised. The distinctions which have been drawn between invaginations of the small intestine and those of the large (to wit, that in the former case the symptoms are usually more sudden and severe, vomiting earlier and more persistent, constipation more complete, discharge of blood per anum more profuse, inflammation more intense, and death more rapid) are no doubt true of most cases, but they are not to be relied upon absolutely; for it occasionally happens that invaginations of the small intestine assume a chronic character, and still more frequently that those of the large take an acute course and even end in the detachment of the invaginated portion. The percentage mortality of intussusception is very large. It must be observed, however, that in arriving at this conclusion we necessarily exclude all those cases in which intussusception is found accidentally after death from other diseases, and those (which we believe to occur now and then) in which intussusceptions form during life and disappear again after the temporary production of symptoms of more or less severity. The average duration of cases fatal from enteritis appears to be about five days.

#### H. *Concluding Remarks in reference to Symptoms*

Before dismissing the subject of intestinal obstructions it may be convenient to consider some of the more important points upon which our discrimination of cases that come before us must depend.

1. *Pain* is a prominent symptom in most cases of obstruction. It is due sometimes to peritonitis, sometimes to colic, sometimes to both of these causes. It varies in intensity in different cases, and may be almost entirely absent. Pain of peritonic quality attends those cases of obstruction which are accompanied by enteritis, and is apt to subside as tympanites supervenes and the fatal event approaches. Colicky pains constitute one of the most characteristic, and at the same time one of the most distressing, symptoms of intestinal obstruction. They come on in paroxysms, and are attended with more or less violent peristaltic movements of the bowel above the seat of obstruction, which are often distinctly visible through the abdominal parietes, and may even from their course and point of apparent cessation furnish a clue to the seat of impediment. These pains may be present in a marked degree in all forms of obstruction, but are most severe and most constant in the cases of longest duration—in those, therefore, in which enteritis is either not present at all or comes on late.

2. *Vomiting* is rarely if ever entirely absent. At first it is merely sympathetic. But after a while it is due to mechanical causes. The bowels above the seat of the obstruction get distended by their contents, which are partly the ingesta, partly the secretions, of the mucous surface. These, by the combined effects of simple overflow, peristaltic action, and pressure from without, regurgitate into the stomach, and then become voided, constituting what is called stercoraceous vomit. This may be peasoup-like and fetid from decomposition, but is never derived from the

large intestine, or truly faecal. Vomiting is generally an early symptom of intestinal obstruction, and in cases of acute progress may continue to the end without cessation. Yet even in some of these it intermits, and may be absent for a comparatively long period. In chronic cases its occurrence is extremely variable, but it generally becomes frequent and stercoraceous towards the close of life. Vomiting is an earlier, more constant, and more severe symptom, in proportion to the nearness of the seat of obstruction to the stomach. In obstruction of the large intestine it is usually long delayed, and may never be a prominent symptom.

3. *Constipation* is, of course, one of the most characteristic phenomena of obstruction; yet faecal matters will often pass with little difficulty even through a tight stricture, especially of the small intestine. Nor must it be forgotten, that generally at the time at which complete obstruction is established, the bowel below contains larger or smaller quantities of faeces, which may be removed naturally or by injections. Scybala are sometimes found post mortem in the large intestine below a complete obstruction of many weeks' standing. Nevertheless, insuperable constipation coming on suddenly is a striking feature of internal strangulation and of the lodgment of gall-stones; insuperable constipation coming on gradually or with premonitory stages, of stricture and compression. In intussusception also there is generally sudden constipation of varying duration; but the invaginated mass, especially when the large intestine is involved, is rarely quite impervious, so that before long, at all events in chronic cases, the transmission of faecal matters is resumed. In intussusception, moreover, blood is apt to be passed at an early period by stool; and is generally passed in abundance when the small intestine is the part affected.

4. *Tumour and shape of belly*.—The belly usually becomes before long tense and tympanitic, in consequence of the accumulation of gas in the parts above the seat of obstruction; and the form of the stomach or of certain convolutions of the bowels may sometimes be distinctly mapped out. Careful attention to the form of the belly, to the visible movements of the organs beneath, and to the sounds elicited by percussion will often aid us in determining the seat of disease. Still, too much reliance must not be placed upon these phenomena, for certain lengths of bowel become in such cases so enormously distended that they not only conceal all the other viscera, but a coil of small intestine may equal in diameter a distended colon, and either of them may simulate the stomach. The detection of a lump is an indication of capital importance. It may be due to the presence of a gall-stone or some other concreted mass lodged in the bowel; it may (in cases of stricture) be a malignant tumour; it may be the evidence of intussusception. If faecal it is liable to variations of form, and is often mouldable like a lump of wax.

5. *The condition of the urine* is a matter of interest. In some cases of obstruction there is almost total suppression; in some there is an abundant limpid discharge. Dr. G. H. Barlow, who first observed this difference, attributed scantiness of urine to the obstruction being high up in the bowel,

and to the consequently little available surface left for absorption; plentifulness of urine to the opposite conditions. Dr. Brinton, accepting Dr. Barlow's facts, referred the deficiency of urine to the abundant vomiting which attends the one class of cases, and the copious secretion of that fluid to the comparative absence of vomiting which is usual in the other class. Mr. W. Sedgwick, however, argues that the diminution or suppression of the urinary secretion is related to the suddenness and intensity of the symptoms, and is due to the influence of the sympathetic system. On the whole there is reason to believe that diminished secretion, which is often only temporary, characterises mainly those cases in which the symptoms are sudden and acute; and almost necessarily, therefore, in larger proportion cases involving the small intestine than cases involving the large.

6. *Duration of life*.—Complete obstruction occurring in the rectum or colon may not prove fatal for several weeks or even several months. Death as a rule supervenes earlier in proportion as the impediment is situated near the stomach. When, however, enteritis is associated with obstruction, then, wherever the obstruction may be, the progress of the case is always rapid, and, dating from the commencement of enteritic symptoms, rarely occupies more than a week, often only three or four days.

7. *Statistics*.—According to Dr. Brinton's figures, based on 500 deaths from obstruction, it appears that in every 100 cases, 43 are due to intussusception, 17 to stricture, 4·8 to impaction of gall-stones, 27·2 to internal strangulation (including, however, all those cases which have been ascribed above to compression or traction), and 8 to torsion or twisting.

### I. *Treatment*

1. The treatment of constipation turns, in different cases, upon very different considerations. A temporary attack may be put right by the use of a simple purge—a dose of castor oil, a black draught, a colocynth pill, or a simple enema. In young babies the mere introduction of the nozzle of the enema tube, or the insertion into the anus of the point of a piece of soft paper rolled into the form of a pencil, is often amply efficacious. When constipation is of a more permanent character it may often be overcome by the mere persistent repetition of daily efforts at some particular time (preferably after breakfast) to evacuate the rectum; or by the habitual use of particular kinds of food, such as brown or bran bread, of a large proportion of fresh vegetables or fruit, or of dried fruit, such as plums and figs; or, again, by the daily use of small doses of mild laxatives, such as a few stewed prunes, a teaspoonful of confection of senna or of castor oil, taken in the morning, on an empty stomach; or by the similar employment of a combination recommended by Trousseau of one-sixth or one-seventh of a grain of podophyllin combined with an equal quantity of extract of belladonna. In some of these cases, a course of iron, strychnia, belladonna, or atropia in small doses, either alone, or combined with mild aloetic or other purgatives which act especially on the lower bowel, is serviceable; as also is the occasional employment of

simple or purgative enemata. Galvanism applied to the surface of the abdomen, or to that and to the anus, is occasionally efficacious. In some cases much more active purgation is needed; and in some it becomes absolutely necessary to dislodge the hard fecal accumulation by the finger, a spoon, or some such instrument, or by the use of repeated enemata, or, better still, by directing a forcible stream of warm water, conducted from a height by means of a tube, into the rectum, and allowing it to play upon the fecal mass for half an hour or so at a time, and thus to cause its disintegration, and either effect or facilitate its removal.

2. The treatment of cases of obstructed bowel must be regulated partly in accordance with what we know or suspect of the nature of the cause of obstruction, partly in accordance with the character of the symptoms present. It may be laid down as a general rule, from which it is highly unsafe to depart, that, whenever the symptoms of obstruction are associated with those of enteritis (whenever, in fact, there is besides obstruction obvious inflammation), the treatment to be adopted is that already recommended for cases of enteritis: namely, the local abstraction of blood and application of fomentations, the use of opium in sufficiently large quantities, the avoidance of purgatives, the administration of food in small portions and in the liquid form, and all those subsidiary measures which are elsewhere considered in sufficient detail. This is the form of treatment that is especially applicable to cases of internal strangulation, impaction of foreign bodies, and jejunal or ileal intussusception.

In those cases, however, in which the symptoms of obstruction come on vaguely and without evidence of association with inflammatory mischief, it is generally advisable to commence the treatment with the administration, either by the mouth or by the rectum, of moderately powerful purgatives, and to persist in this treatment until, by their failure to act, and by their causing vomiting, and painful but fruitless peristaltic movements, their inefficacy is distinctly shown. It sometimes happens that, after drastic purgatives have failed, a large dose of some simple laxative, such as castor oil, acts with singular efficacy. In aid of this treatment, hot baths, fomentations, ice or electricity to the surface of the belly, and voluminous enemata of gruel or water, administered by the long tube, may severally be employed. If these measures are without avail, it is generally advisable to give the bowels rest, and to relieve pain by the repeated use of adequate doses of opium or belladonna; the persistence in which treatment will, by relieving spasm or otherwise promoting the return of some length of bowel to a comparatively healthy condition, not unfrequently result, after a shorter or longer time, in an effectual and sufficient evacuation. If this treatment fail in its turn, it may be necessary again to solicit the action of the bowels by the employment of purgative medicines, enemata, and the like. Such is the routine that must generally be followed in cases of simple obstruction, in which the cause of obstruction is obscure; and in many cases also even when the cause is distinctly ascertained.

When, however, the obstruction depends on the presence of a stricture in the rectum or sigmoid flexure, the persistent use of powerful purgatives is scarcely judicious; copious and frequently repeated enemata are then of especial value. If the stricture be within reach it may admit of dilatation by the bougie. Again, when the obstruction is due to an ileo-cæcal or a colic intussusception, powerful purgation is likely to do more harm than good; large enemata, however, are occasionally efficacious in causing the reduction of the intussuscepted bowel. But the most powerful, and apparently the most efficacious, form of enema for this purpose appears to be the inflation of the large intestine with air. Lastly, when, in cases of obstruction, the bowel is working with visible violence and pain; or we have reason to believe that (as in the course of those cases in which the invaginated portion of bowel is discharged per anum, and in all cases where there is, and has been for some time, much tympanites) the bowel is enfeebled and in danger of rupture, purgatives must be religiously avoided.

In most cases where there is reason to believe that the cause of obstruction, whatever it may be, is seated in the large intestine, the long enema tube should be employed, partly for diagnostic purposes, partly for treatment. With care, and by injecting a small quantity of fluid so as to distend and straighten the bowel whenever the point of the instrument becomes arrested, the tube may without difficulty be passed along the bowel for a distance of two or three feet or more, and then either fluid may be injected or liquid matters may be withdrawn. By such means stricture may occasionally be relieved, twisted bowels may sometimes be untwisted and emptied, and faecal accumulations high up may be disintegrated or dislodged.

In the course of many cases of obstruction, the question of relieving the patient by surgical means must necessarily arise. The time at which an operation should be performed, and the nature of the operation to be performed, are of course matters of grave importance. It may be accepted as a general rule that when once the desirability of this procedure has been recognised, the earlier recourse is had to it the better. Exploratory operations were formerly rarely successful. It has been proved, however, of late years that with suitable precautions the abdomen may be laid open and explored with very little risk to life; and hence objections to this procedure on the score of risk may fairly be ignored in cases of obscurity and grave danger. But there are some circumstances under which operations are not only justifiable, but imperatively demanded. No patient who has either a rupture (even if there be no evidence of strangulation in it) or a hernial sac, or any trace or hint of any affection of the sort, should be permitted to die with symptoms of obstruction without having the chance given him which an exploratory operation at the suspected site affords; nor should we, with the object of unfolding the involved bowel, hesitate to perform gastrotomy in cases of ileo-cæcal intussusception which have resisted other modes of treatment. Other operations which are often serviceable in prolonging life, and are some-

times curative, consist in opening the bowel and forming an artificial anus in some convenient spot above the seat of obstruction. Such operations are especially applicable when the large intestine is the seat of disease. If the obstruction be in the rectum or sigmoid flexure, the opening should be made in the left loin into the descending colon; if above these portions of the bowel, then in the right loin and into either the cæcum or the ascending colon. If the obstruction be in the cæcum itself, or in the small intestine, Littré's operation is alone available. This consists in laying open the peritoneal cavity, and then opening the bowel (having first brought the part to be divided to the surface) above the seat of stricture. The lips of the wound in the intestine must be attached by sutures to those of the incision in the abdominal walls. It is an interesting fact that not unfrequently the opening of the descending colon, with the establishment of an artificial anus, is followed by the re-establishment of the normal channel, owing doubtless to the stricture not being a tight one, and to the complete obstruction being immediately due to the impaction of a solid mass of faecal matter. The enormous gaseous distension of the bowel which often takes place in obstruction is a cause of great discomfort, and even adds to the patient's risks. It may be relieved by puncturing the distended gut through the abdominal parietes with a grooved needle or fine trocar and cannula. The operation is attended with little or no danger.

---

## XVII. ASCITES (*Abdominal dropsy*)

*Causation and morbid anatomy.*—The above terms are applied to the accumulation of serum within the peritoneal cavity. Ascites is an accompaniment or sequela of many different diseases; but depends immediately on some condition which modifies the action of the capillary vessels or lymphatics of the peritoneal membrane. This may be either some morbid process going on in the peritoneal tissue; some impediment to the flow of blood through the portal vessels; or some disease influencing the systemic circulation generally.

1. More or less effusion of serum attends ordinary acute peritonitis. But such accumulations are rarely abundant, and generally soon disappear. Chronic peritonitis, on the other hand, is a common cause of persistent and progressive ascites, and especially perhaps those forms of chronic peritonitis which occur in women in connection with inflammations of the pelvic organs and the growth of ovarian cysts. In some of the latter cases the dropsy is due to the rupture of cysts and the discharge of their contents into the peritoneal cavity. Tuberculosis and malignant disease of the peritoneum are other frequent causes of ascites.

2. Impediment to the flow of blood through the portal system, and consequent ascites, may be referrible to direct compression of the portal trunk by cancerous, aneurysmal, or hydatid tumours arising external to the liver, or by tumours of various kinds originating in its substance, and

especially by cancerous or fibroid growths occupying the lesser omentum and extending thence into the liver along the capsule of Glisson. Most commonly, however, they are caused by general diseases of the liver, involving the hepatic capillaries and the minute veins which open into and emerge from them. Of these cirrhosis is the most frequent and important. But the simple induration and congestion which constitute the 'nutmeg liver' may have the same effect, as also possibly may lardaceous degeneration. The compression of the liver by a fibroid capsule of inflammatory origin may act in the same way as cirrhosis.

3. Among the diseases by which dropsical effusion into the belly, as a part of general dropsy, may be caused, are heart-disease, chronic affections of the lungs, and certain forms of renal disease; to which may probably be added various cachexiæ and simple anæmia. In many of these cases the ascitic accumulation is proportionate only to the dropsy of other parts. In some, however, it becomes excessive, while the dropsy elsewhere undergoes but little increase. When this is the case there is generally some local complication (coming under the first or second group of causes which have been considered) to which this disproportion is attributable.

The amount of fluid present in ascites may vary between a few pints and four or five gallons. Its quality also may vary. It is usually slightly viscid, transparent, of a yellowish or greenish tinge, alkaline, and containing both albumen and fibrinogen, and often fibrinous clots. It is sometimes very viscid (especially in cases of ovarian tumours or colloid cancer), sometimes opaline from the presence of inflammatory or other products, or turbid and discoloured with altered blood.

*Symptoms and progress.*—The accumulation of fluid in the abdominal cavity causes its gradual distension, and sooner or later obstructs the intra-abdominal veins, especially those connected with the lower extremities, impedes the movements of the diaphragm, and interferes injuriously with the healthy action of the abdominal viscera. It modifies also the patient's gait, making him walk like a pregnant woman, with his legs wide apart, and his head and shoulders thrown back. The ascitic abdomen is large, uniformly rounded, with a tendency to spread or bulge in the flanks as the patient lies on his back, tense, and more or less smooth and shining, and often presents distended superficial veins and that linear atrophy of the skin so common in pregnancy. The stomach and intestines tend, of course, to float on the surface of the fluid; and hence generally the highest part of the abdomen is resonant, the more dependent parts dull—the line of demarcation between them being for the most part well defined and horizontal, but varying with the varying positions which the patient assumes. The liver, which is of higher specific gravity than dropsical fluid, often retreats distinctly from the anterior surface of the abdomen and from the diaphragm—a stratum of fluid with sometimes a loop of bowel occupying the interval. The presence of fluid is further indicated by the peculiar thrill experienced by the hand laid flat on the abdomen, when a ripple or wave is produced in the ascitic fluid by a slight tap or fillip applied to some other part of the abdominal surface.

These signs are not always present, or at any rate easy to recognise ; and not unfrequently tumours and other conditions simulate or mask abdominal dropsy, and interfere with the formation of an accurate diagnosis. The fluid may be so small in quantity that it occupies the pelvis only ; it may then, however, be detected by making the patient rest on his knees and elbows so as to allow it to gravitate to the neighbourhood of the umbilicus. It may be so abundant that the stomach and bowels fail to reach the surface ; in which case the dulness may in all positions of the body continue general, excepting, perhaps, in the course of the ascending and descending colon ; but here fluctuation will almost certainly be well marked. Or adhesions may limit the distribution and mobility of the ascitic fluid ; or there may be adventitious cystic or other growths in the abdominal cavity ; or the parietes may be fat or œdematous.

In most cases ascites causes pretty uniform distension ; but in some where pouches exist, or the parietes are thin and yielding at certain points, this uniformity is interfered with. Thus hernial sacs, whether at the umbilicus or at the groin, get distended with fluid ; and in females the recto-vaginal pouch sometimes becomes so much dilated that it protrudes through the vulva in the form of a tumour, carrying with it as a covering the posterior wall of the vagina.

œdema of the lower extremities and genitals is a common and early accompaniment of ascites. It sometimes occurs so early that the patient observes it before his attention is particularly directed to the condition of his belly. It is doubtless due (when thus limited and unconnected with cardiac or other equivalent disease) to the pressure exerted by the ascitic fluid on the iliac veins, and is generally fairly equal in the two limbs. Shortness of breath is an early symptom. It depends on the mechanical impediment which the accumulated fluid opposes to the descent of the diaphragm, and increases, therefore, with the increase of accumulation. It is sometimes so slight that the patient only observes it when he exerts himself ; sometimes it is exceedingly distressing ; and it is usually increased when he lies down. The lower parts of the lungs are apt to become empty of air and collapsed. Abdominal discomfort or pain, mainly in the lumbar regions and about the umbilicus, generally arises in the course of the affection. This is often of an aching, flatulent, or colicky character, and is probably due in some degree to the pressure which the fluid exerts on the hollow viscera and other organs. Sometimes it is peritonitic, and indeed the supervention of acute or subacute peritonitis is not rare in the later stages of ascites. Although early in the affection there may be no visible morbid condition of tongue, and neither thirst nor loss of appetite, the tongue and the digestive functions become after a while variously and more or less seriously affected. Diarrhœa especially is a by no means uncommon complication ; and is due, sometimes to the same impediment to the portal circulation that causes the ascites, sometimes to slight dysenteric disease. There is generally also dryness of skin and diminution of the urinary secretion. Various other symptoms are usually presented by ascitic patients ; but they are for the most part

the symptoms of the morbid conditions on which the ascites itself depends, and are sufficiently considered elsewhere.

*Treatment.*—The treatment of ascites merges, in a large proportion of cases, in the treatment of the diseases out of which it arises. Still there are many cases in which sooner or later special treatment directed against the ascites itself is demanded. To promote the absorption and removal of the dropsical accumulation there are good theoretical reasons for the employment of those remedial measures which increase the discharges from the skin, the kidneys, and the bowels. For diaphoretic purposes we must not forget the value of the hot bath, the vapour bath, and the Turkish bath. Among diuretics must be especially signalised iodide of potassium, copaiba, and the combination of crude mercury, fresh squills, and digitalis. Of purgatives, those which promote watery evacuations are obviously the most likely to prove efficacious. We are bound, however, to state that, while acquiescing in the importance of restoring, so far as may be, or of maintaining, the healthy action of the skin and kidneys, and of acting freely on the bowels, we have seldom been satisfied of the efficacy of such measures in causing the removal of the dropsical fluid. And indeed, as regards purgatives, we have frequently had to discard them because, while not distinctly benefiting the dropsy, they were in other ways obviously affecting the patient's health injuriously. Further, the diarrhœa which comes on spontaneously in the course of ascites is not only not curative, but difficult to arrest, and often of bad augury. In a large number of cases, no doubt, all medicines are alike inefficacious; but there are many in which the general improvement of the patient's health, no matter how brought about, is followed by the subsidence of the dropsy. Tonics, of which quinine, iron, and cod-liver oil are probably the best, are especially valuable in this respect. It is certain that they are often well borne by ascitic patients, and that, even when not well borne at first, a little judiciousness in their selection and mode of exhibition renders them tolerable; and it is certain that often, under their use, patients not only improve in general health, but lose in part or wholly their dropsical accumulations, and that occasionally their recovery is permanent, and permanent even after the performance of paracentesis. Local applications to the abdomen are only needed to relieve pain or uneasiness; but when the abdominal distension becomes so great as to cause the patient serious suffering or distress, the fluid must be removed by tapping. This operation is usually delayed as long as possible, and on the whole, no doubt, properly so. There is, nevertheless, reason to believe that the beneficial effect of remedies is sometimes exerted much more markedly immediately after it than while the abdomen is full of fluid. Paracentesis, though usually a harmless operation, is sometimes followed by peritonitis. It is rarely of even temporary benefit in the ascites which accompanies malignant disease.

---

## XVIII. HEMORRHAGE. HÆMATEMESIS. MELÆNA

*Definition.*—When blood is vomited the affection is termed *hæmatemesis*, when blood is passed by stool and is of a black colour, as it usually then is, the term *melæna* is applied.

*Causation.*—Gastro-intestinal hemorrhage may be due : either to the influence of diseases, such as the infectious and malarious fevers, purpura, and scurvy, in which the quality of the blood is altered ; or to mechanical impediment to the passage of blood through the portal system or any of its tributary branches ; or to congestion, inflammation, breach of surface, or morbid growths, involving any part of the mucous membrane. It is said occasionally also to occur vicariously of menstruation.

Profuse hemorrhages arise mainly from chronic ulcers of the stomach or duodenum, or from general hyperæmia of the gastro-intestinal mucous membrane, due either to cirrhosis of the liver or to obstruction of the portal trunk. Besides these causes must be especially named carcinomatous and villous growths of the stomach and bowels, and the rupture of aneurysms. Copious hemorrhage also sometimes takes place from typhoid or dysenteric ulcers. But it must not be forgotten that hemorrhage, which must be regarded clinically as hæmatemesis, often comes from the œsophagus, and may then be due to malignant disease causing perforation of the œsophageal, intercostal, or other neighbouring vessels, or to the rupture of aortic or other aneurysms or of dilated veins ; and, further, that blood vomited from the stomach may have been previously swallowed, as sometimes happens accidentally in epistaxis, or designedly and for the purpose of deception.

*Symptoms and progress.*—It may be taken as a rule to which there are few exceptions that blood, discharged from any part of the alimentary canal below the duodenum, is voided solely by the anus with the fæces. And although hemorrhage from the stomach, duodenum, or œsophagus is, no doubt, in a large number of cases, attended with hæmatemesis, it must not be forgotten that in almost all cases a larger or smaller quantity of the blood which finds its way into the stomach is passed onwards into the bowels, and that in some the whole bulk of it is thus transmitted. These are facts of great importance, inasmuch as abundant gastro-intestinal hemorrhage may take place, and may continue for some length of time, causing progressive and extreme anæmia, without revealing its presence to the patient himself or to the medical man who fails to investigate the condition of the stools.

The recognition of blood in the vomit or fæces is not generally difficult. If it escape in small quantity, into either the stomach or the intestine, it mingles with the other contents of the viscus, which acquire a grumous, and coffee-ground, sooty, or pitchy character. And, however abundant it may be, the longer its detention in the alimentary canal, or the longer the journey which it has to perform along it, the darker and blacker as a rule it appears at the time of its discharge. Under other circumstances it may be voided almost pure, sometimes fluid, sometimes coagulated, and,

though generally of a dark hue, in some instances of a vivid arterial tint. If there be a doubt as to the presence of blood, the microscope will probably clear it up. When, however, the blood-corpuscles are wholly destroyed, and blood-pigment alone is left, some difficulty of identification may be experienced, and it may be necessary to have recourse to chemical investigation or to the spectroscope. It is, of course, important not to confound the discoloration of the vomit and feces, due to articles of diet (port wine and the like), to drugs (iron, bismuth, and mercury), or to bile, with that dependent on the presence of blood.

Small hemorrhages are in themselves of little moment; their frequent repetition, however, necessarily tends to induce more or less marked anæmia, and the various symptoms which attend anæmia. Large hemorrhages, on the other hand, are alarming in their immediate symptoms and of extreme danger to life.

The occurrence of copious bleeding into the gastro-intestinal canal is usually attended with sudden faintness; sometimes indeed the patient falls down insensible and convulsed. The phenomena are those of the rapid loss of a large quantity of blood, but are also not unlike such as may attend sudden hemorrhage into the substance of the brain, or the commencement of an epileptic seizure. From this attack of faintness the patient usually soon recovers somewhat; and then, if the hemorrhage have taken place into the stomach, he probably ere long vomits a more or less considerable quantity of blood (sometimes as much as a quart or two at one time or within a short period), and later on passes a greater or less bulk of pitchy matter by stool. In some cases, as has been pointed out, no hæmatemesis takes place, but melæna alone supervenes. In some the patient dies collapsed before any of the effused blood has had time to be discharged either upwards or downwards.

The further progress of such cases depends largely upon their cause. But without taking the question of cause into consideration, in some instances the patient dies from sudden faintness, or falls into a condition of collapse from which he never recovers; in some he is suffocated by the entrance of blood into the air-passages; in some the hemorrhage is repeated over and over again, the patient becomes excessively anæmic, the usual symptoms due to recurrent losses of blood ensue, and at length death occurs; in some, of course, he makes a good recovery, and possibly never has a return of his malady. A curious occasional phenomenon, in connection with profuse hæmatemesis, to which Lenke calls special attention, and which we have witnessed, is the sudden occurrence of double amaurosis; in which the ophthalmoscope reveals only unnatural whiteness of the optic nerve and narrowing of the retinal arteries, and which appears to be for the most part incurable.

*Treatment.*—An accurate diagnosis of the cause and seat of bleeding in hæmatemesis and melæna is very important in reference to treatment, and must rest partly on close observation of the phenomena which the case presents, partly on a careful inquiry into its history, but is in many cases, at least for a time, absolutely impossible. There are certain measures,

however, which under any circumstances should be taken. The patient should be placed and kept in the supine position, forbidden to make muscular exertion, and guarded from all causes of mental excitement; the stomach and bowels should be kept as far as possible at rest, and hence generally purgatives and emetics, solid food and stimulants, should be eschewed, and fluid food should be given in small quantities; and the force of the circulation should be restrained, a result which is in some degree attainable by perfect quiescence of mind and body, by keeping the outer surface only moderately warm, and by the use of certain medicines, of which digitalis and lead are among the most valuable. Simple styptics are not, as a rule, of much use in restraining hemorrhage, unless they can be directly and well applied to the bleeding surface: and hence their value is not generally very great in restraining gastro-intestinal hemorrhage. It can, however, at least do no harm to employ them. Among such remedies may be named perchloride of iron, sulphuric acid, tannic acid, and turpentine. Ice and ice-cold drinks are serviceable, as well for their astringent as for their sedative influence. Ice may also be applied with benefit to the surface of the chest or abdomen. When we have reason to believe that the hemorrhage is due to an overloaded state of the portal system, it is commonly regarded as injudicious, if not useless, to attempt to restrain it. And indeed it is often recommended that the bowels should then be acted on by repeated and tolerably strong purgatives, with the object of relieving the distended vessels. It must be remarked, however, that this variety of gastro-intestinal hemorrhage is probably the most frequently fatal of all varieties; and that death, when it occurs, is generally due simply to loss of blood. It seems scarcely reasonable, therefore, in such cases to promote, by stimulating the bowels, a kind of relief which is so dangerous to the patient's life, and which, even without such stimulation, is only too often fatal. The blood, indeed, which comes away is probably derived mainly, if not entirely, not from the overloaded portal system, but from the systemic arteries which feed that system, and directly from the congested capillaries distributed to the mucous surface. We should therefore recommend the employment not only of cold and of astringents to the alimentary tract, but of all those measures which have been noticed as tending to soothe and regulate the circulation. The further treatment of gastro-intestinal hemorrhage must depend on the nature of the primary disease, from which the patient is suffering, and on the special features which his case from time to time exhibits.

---

### XIX. DYSPEPSIA (*Indigestion*)

*Definition.*—No account of the diseases of the alimentary canal and its appendages would be deemed complete unless it comprised some separate consideration of dyspepsia or indigestion, that most common and fashionable of all complaints. It is difficult, however, to know how to deal with it; for, on the one hand, it includes within itself all those functional

derangements of the stomach which attend and help to characterise the various diseases of that viscus, and many of those of the rest of the alimentary canal, and of the glandular organs opening upon its mucous surface, together with such derangements as are connected with general morbid states of the system, and such as depend upon the quality, quantity, and condition of the alimentary matters taken into the stomach; while, on the other hand, it is often regarded as the collective name for groups of morbid symptoms, referrible to the stomach, which are independent of any discoverable local or constitutional disease. In the former point of view, dyspepsia ranges throughout the whole domain of clinical pathology; in the latter, the advance of pathological knowledge tends day by day to restrict more and more the limits of its applicability. To discuss dyspepsia in the former sense would be utterly beyond the scope and purport of the present work; to consider it strictly in the latter sense would be at once difficult and unsatisfactory. The most convenient course will probably be to consider briefly: the causes of dyspeptic symptoms; the several local phenomena which constitute dyspepsia; the sympathetic and other consequences to which dyspepsia may give rise; and, lastly, its medical treatment.

*Causation.*—The causes of dyspepsia may be conveniently divided into three groups:—namely, those connected with the ingestion of food; those connected with morbid conditions of the stomach; and those connected with derangements or diseases of other organs or of the general system.

1. In the first group are comprised many pregnant causes of indigestion—causes, some of them, none the less important because they involve the habitual and conscious transgression of obvious sanitary laws. Among them may be included the following:—*Imperfect mastication*, or the bolting of food, usually arising from undue haste in eating, or from defect or absence of teeth, or from soreness or paralytic conditions of the mouth. *Active bodily or mental exertion* immediately before or after a meal. *Over-eating*, whether this consist in a single surfeit, or in that habitual indulgence to excess of which so many of us are guilty, and which is especially injurious if it go along with sluggish sedentary habits. *Insufficiency of food.* *Improper arrangement of meals*, such, for example, as the taking of one meal only during the twenty-four hours, or the crowding of all one's meals within a period of eight or ten hours, leaving the remainder of the four-and-twenty without any, or the practice (included to some extent under the last head) of interpolating meals between the more important meals, and thus refilling the stomach ere it has had time to rid itself of its previous load. *Injudicious admixture of foods.* Of the frequently injurious influence of the admixture of many different kinds of even wholesome articles of diet there can be no doubt; it is difficult, however, to lay down any exact rule in regard to this matter, for, within limits of moderation, variety is conducive to health, and the too strict limitation to one or two kinds of food not unfrequently proves as detrimental as excessive heterogeneous indulgence. The use of indigestible

or *unwholesome aliments*. This might serve as the text for a very wide discussion; it is sufficient, however, to point out here that, in addition to substances which may be regarded as generally injurious, there are many which become injurious only from the circumstances or conditions under which they are taken, or from temporary or permanent peculiarities in the constitution of the sufferer, or in the condition of his digestive organs; thus sometimes mutton, pork, veal, game, or shell-fish disagrees, sometimes pastry, milk, or eggs, sometimes different forms of vegetables or fruit, sometimes tea or coffee. To these causes may be added the abuse of alcoholic stimulants, or of tobacco, and the excessive indulgence in condiments, and perhaps also the habitual abstention from certain kinds of food which are essential to the due maintenance of the integrity of the organism.

2. The second group of causes (that which embraces the morbid conditions of the stomach itself) is necessarily also a very extensive group. It includes, moreover, all those morbid conditions which have already been described, and the presence of any one of which removes the case from among the dyspepsia in the restricted sense of that term. The following is a list of the more obvious of the conditions here adverted to:—*Catarrhal inflammation and congestion* of the mucous membrane, which are amongst the most persistent causes of dyspeptic symptoms, and are often the immediate cause of such symptoms attending the various alimentary abnormalities just enumerated; *Gastric ulcer*; *Carcinomatous and other morbid growths*; *Abnormal dilatation of the stomach*, whether this be of primary origin, depending upon inherent feebleness of the walls or habitual over-loading of the organ, or whether it be secondary to pyloric or other obstructions to the onward passage of alimentary matters; *Diminution in size*, whether arising from the gradual contraction of infiltrating growths of the gastric walls, or from long-continued abstinence, or from spasmodic action of the muscular coat referrible to irritability of the mucous surface or other sources of reflex action; *Degenerative changes* of the mucous membrane, such as may result from chronic catarrhal inflammation, or the abuse of alcohol, or may arise in the course of chronic wasting diseases; and, lastly, functional derangements, including irritability, and excess, diminution, or derangement of the gastric secretions.

3. The third group of causes again is one of great extent. It includes: all those conditions of the alimentary canal—constipation and the like—which react on the functions of the stomach; all those morbid states of surrounding organs which lead to pressure on the stomach and interference with the performance of its duties; all those lesions of the portal system, lungs, heart, and kidneys, which, by impeding the circulation, induce congestion or other abnormal gastric conditions; all those disturbances of the nervous system (among others powerful mental impressions or emotions, and the reflex phenomena of early pregnancy) which influence the actions of the stomach; and, further, all those general diseases—*anæmia*, pulmonary phthisis, fevers, and innumerable others—of which

difficult, painful, or faulty digestion forms an appreciable, if not a prominent, symptomatic feature.

*Symptoms.* 1. *Referrable to the stomach.*—The symptoms which attend and indicate dyspepsia are to a large extent those which also accompany in a greater or less degree the various organic lesions of the stomach. They comprise derangements of appetite, derangements of sensation, flatulence and eructation, nausea and vomiting.

The *appetite* in dyspeptic patients is very variable. In some cases it remains but little affected, or there is simply a distaste for certain articles of diet; or, without there being any actual distaste, experience shows that certain alimentary matters formerly taken with impunity now induce various discomforts. In many cases there is loss of appetite, and occasionally this amounts to absolute repugnance to all forms and varieties of food. In many cases, again, a persistent sense of uneasiness or emptiness, with constant craving for food, is a marked phenomenon: it occasionally happens that the appetite is absolutely increased; more frequently, however, the craving is changed by the ingestion of even small quantities of food into some other sensation of discomfort, which brings the meal to a speedy close. Now and then, and especially in hysterical females, the appetite becomes depraved: the patient not merely craving for aliments which are of an unwholesome character, but swallowing earth, coals, chalk, or other substances which are either wholly devoid of alimentary virtues, disgusting, or absolutely injurious. Thirst may or may not be present.

The *abnormal sensations* which attend dyspepsia are of different kinds. There is generally uneasiness or pain. A sense of weight, sinking, fulness, shooting, aching or burning, referred to the pit of the stomach or some neighbouring part, or to the inter-scapular region, is rarely absent. In some cases this comes on mainly when the stomach is empty, and disappears under the influence of a meal; in some it comes on immediately after food, and lasts during the whole period of gastric digestion; in some it is more or less constant, being present when the stomach is empty, but becoming aggravated or modified after a meal. In other cases pain comes on some little time after food has been received into the stomach, it may be in the course of a quarter or half an hour, or after the lapse of two, three, or four hours. Another form of gastric pain is described as connected with dyspepsia—namely, a pain of great intensity, frequently likened to that of cramp, which comes on at irregular and often rare intervals, which lasts a variable time, and is usually attended with marked symptoms of faintness or collapse, and often in women with hysterical phenomena. This pain, which is not uncommon in gouty persons, occupies the usual position of gastric pains, but shoots in various directions upwards into the chest and downwards into the abdomen. There is no doubt that this variety of gastrodynia is largely confounded with pain originating in other than gastric sources, and especially with that due to the passage of gall-stones. Neuralgia of the stomach, sometimes persistent but usually coming on in paroxysms, is a common symptom of *tabes dorsalis*. Epigastric tenderness is not usual.

*Flatulence and eructation* are generally complained of by dyspeptics in a greater or less degree. Flatulence usually goes along with sense of fullness or distension of the stomach, and other of the uneasy or painful feelings which have been considered. The accumulation of gas is indicated also by actual distension of the epigastric region, and the occurrence of gurgling, and other noises within the stomach; it moreover gives rise to eructation. Eructation, which is generally attended with more or less relief to the patient, is often noisy, and effected with powerful and uncontrollable spasmodic action of the muscles. The amount of wind thus discharged is sometimes enormous; and at the same time it is so sudden in its evolution that it has been assumed to be secreted by the mucous membrane of the stomach and bowels. Of this, however, proof is wanting; and indeed there can be no doubt that it is really derived from decomposition of the food. The gases consist of carbonic acid, hydrocarbons, and in some cases sulphuretted hydrogen. Together with these, small quantities of the contents of the stomach are not unfrequently brought up. In some cases the quantity of matter thus discharged without sensation of sickness or material effort is very considerable; and the process by which it is returned is sometimes termed rumination.

*Nausea and sickness*, again, are frequent symptoms of dyspepsia, and are sometimes exceedingly distressing. In many cases of functional dyspepsia, as in that of pregnancy, nausea often goes along with increased appetite. Sickness is usually preceded by nausea, and occurs at different times and with various degrees of severity. In some cases it comes on when the stomach is empty; more frequently it occurs shortly after ingestion; sometimes it does not happen until an hour or two after a meal; and occasionally it takes place at irregular and long intervals. The material vomited presents considerable variety: in some cases it is simply the food but little altered; in others it is an alkaline ropy mucus; in others it consists mainly of the ordinary acid juices of the stomach; in others it is a neutral watery fluid having many of the characters of the salivary secretion. In other instances (and especially when the vomiting does not take place until long after the ingestion of food) the vomited matters have undergone fermentation: they are acid from the development of acetic, lactic, and butyric acids, and present, on standing, a brownish frothy scum and a more or less abundant sediment; or else they have undergone putrefactive changes and have an offensive, occasionally rotten-egg-like, occasionally faecal, odour. The vomit presents as much variety in amount as in quality; sometimes it is scanty, and little more abundant than occurs in eructation; at other times it is discharged in enormous quantities. The latter occurrence is most frequent when the vomiting comes on some hours after a meal, or at irregular and comparatively long intervals, and therefore in cases of obstructive disease of the pylorus, or when the stomach, from whatever cause, is abnormally dilated and sluggish or enfeebled. It may be observed that vomiting immediately after food is generally indicative of irritability of the stomach; that the discharge of abundant ropy mucus usually implies the presence of inflam-

mation; that fermentative and putrefactive changes point to long retention of alimentary matters in the stomach, and possibly also to some defect of relation between the quantity of food ingested and the quantity of gastric fluid secreted; and that always after long-continued vomiting the contents of the duodenum, inclusive of bile, regurgitate into the stomach, and thus mingle with the vomit. When fermentation takes place the torula cerevisiæ may always be discovered in great abundance in the vomited matters, and it is usually under similar circumstances that the sarcina ventriculi also may be recognised. It may be added that vomiting is a common incident in affections of the brain and in the so-called 'crises gastriques' of locomotor ataxy.

The term *pyrosis* is generally used of those cases in which a clear fluid is vomited or eructated, for the most part in connection with more or less severe epigastric pain, and at times when the stomach is empty, or nearly empty, of food. The quantity of fluid brought up within a short time may vary from a few teaspoonfuls to several pints. It is usually neutral, but may be alkaline or acid. Both by Budd and by Frerichs this fluid, when of neutral reaction, is looked upon as being saliva which has been swallowed. Pyrosis is not unfrequently connected with organic disease of the stomach; but in its most typical form is either functional or due to the constant use of certain irritating articles of diet. It is said to be especially common among the lower classes in Scotland and Lapland, and to be dependent on the quality of their food. In a typical case under our own care, the fluid was proved by chemical examination to be saliva. Moreover, it was ascertained that it was certainly not vomited, but simply accumulated in the throat, whence it was discharged without effort. The patient had had symptoms of ulcer of the stomach and profuse hæmatemesis; and as these disappeared, the water-brash came on. It seemed probable the profuse discharge of saliva was a reflex phenomenon.

2. *Referrable to other organs.*—Among the many secondary phenomena of dyspepsia, those connected with the remaining regions of the alimentary canal first claim attention. The tongue varies in character; it is sometimes clean and healthy, sometimes pale and flabby, sometimes coated, sometimes cracked or fissured. The bowels are for the most part constipated, but there may be persistent diarrhœa, and not unfrequently there is considerable irregularity of action. In some cases of indigestion, attended with looseness of bowels, undigested food in more or less abundance is found in the stools. It is obvious that in these cases the passage of the contents along the bowel is exceedingly rapid; and in many of them, according to Trousseau, whose experience is confirmed by that of Dr. Wilson Fox, there is at the same time large appetite, with rapid escape of food from the stomach, and rapid consequent renewal of appetite. Trousseau assumes that there is excessive irritability of the muscular walls of the stomach and bowels, and that it is on this account that the food is carried too swiftly onwards. The urine is frequently affected, and may contain an excess of phosphates, oxalates, or urates, the last not unfrequently being deposited as a lateritious sediment. The action of the

heart is commonly quickened, but is sometimes slower than natural, and often variable. Dyspeptic patients are liable to palpitation and irregularity of action, coming on especially after meals or in the night. Dyspnoea is apt to attend the attacks of palpitation; and a variety of asthma has been referred to the presence of indigestion. Dyspeptics are peculiarly prone to certain forms of skin disease, such as urticaria, erythema, lichen, and eczema, but above all, perhaps, to acne rosacea, and other allied conditions manifesting themselves upon the nose and cheeks. Elevation of temperature and other distinct febrile symptoms are no necessary features of dyspepsia; but they may appear if the dyspepsia be connected with inflammatory affections of the stomach. The influence of dyspepsia and of other morbid conditions of the stomach on the functions of the nervous system is very remarkable. Vertigo, headache, intolerance of light and sound, depression of spirits, irritability, hypochondriasis, sleeplessness, and various forms of neuralgia are all of common occurrence. The severer forms of dyspepsia, and especially those in which there is much sickness, are usually associated with more or less debility and emaciation. Indeed, purely functional affections of the stomach, attended either with total loss of appetite or with constant vomiting after food, occasionally induce a degree of emaciation and debility rivalling that which one meets with in the last stages of carcinoma of the cardia or pylorus, or of pulmonary phthisis with intestinal ulceration. On the other hand, it is often curious to observe how, notwithstanding incessant vomiting, patients retain a fair amount of plumpness.

*Treatment.*—The treatment of dyspepsia is a subject of considerable importance and no little difficulty, and demands a good deal of firmness, *savoir faire*, sound judgment, and readiness of resource on the part of the physician, and often at the same time no little trust and resolution on the part of the patient. The first thing to be done is to ascertain as far as may be the circumstances to which the dyspepsia owes its origin, or those which determine its continuance, and, if possible, to cure or obviate them. With this object, it may be of essential importance: to insist on the proper comminution of food, to see that the teeth are in good order, and if not that they are supplemented or replaced by false ones, or that artificial mastication is employed, and that the patient gives ample time to his eating; to regulate the distribution of the meals, so that, if they be full meals, they shall be separated by intervals of four or five hours at least, or if, from any circumstance, the patient is compelled to take only small proportions of food at any one time, the intervals between them shall be correspondingly reduced; to regulate the quantity of food taken at each meal and daily, in the sense of neither letting it fall below what is required, nor of permitting any great excess; to insist that the food taken shall be wholesome and readily digestible, and that especially any article of diet which experience has shown to be injurious shall be strictly abjured. There are considerable differences in regard to the articles of diet which are most suitable for different dyspeptics; and, in order to treat successfully, it is often important to study each patient's peculiarities in

this respect. It may be stated generally, however, that all rich and greasy compounds and fat are likely to disagree; that fish, flesh, and fowl (whichever be selected) should be well cooked; that raw vegetables should be eschewed; that in a large number of cases (and especially those in which the stomach is irritable or inflamed) milk and farinaceous foods and eggs are of especial value; that ripe fruits are admissible and often beneficial; and that alcoholic beverages should be only moderately indulged in. In many cases total abstinence from alcohol is imperatively demanded. Again, it is always important: to ascertain the morbid condition, if there be any, under which the stomach is labouring (if inflammation, ulcer, or growth of any kind be present, if there be obstruction at the pylorus or at the cardia, if the stomach be dilated or contracted, and so on); and to determine the treatment in accordance with the nature of the lesion which is present. It is of equal importance to ascertain whether the dyspeptic symptoms are secondary to any constitutional disturbance, such as anæmia, phthisis, or gout, which happens to be associated with them, in order that we may direct our treatment to the relief or cure of the essential disease.

The above remarks are not intended to distract attention in any degree from the actual symptoms which cause the patient's sufferings. These generally need special treatment; but, guided by the principles above laid down, we may in most cases so select or so combine our remedies as, on the one hand, to relieve local symptoms, on the other to remedy the conditions out of which the dyspepsia has arisen.

*Loss of appetite* is often very difficult of treatment. It may, however, in some cases be overcome by the use of vegetable tonics, especially gentian, quassia, calumba, or the liquid extract of cinchona, in combination with small quantities of rhubarb, aromatics, and an alkaline carbonate; or by the employment of quinine, strychnia, or iron, or (if there be constipation) of aperients, especially rhubarb and aloes, in combination with aromatic bitters. But food has often to be administered when the patient has not only no desire, but possibly even a loathing, for it. It is then necessary either to study the patient's fancies by making frequent variations in the food which is placed before him, or to administer food of a wholesome and suitable character in small quantities and at short intervals. It is sometimes necessary indeed to employ nutrient enemata, and for a time partially or altogether to discontinue the use of food by the mouth.

*Gastric uneasiness or pain* needs different treatment according to the circumstances under which it arises or the conditions to which it is immediately due. When it occurs mainly during the period in which the stomach is empty, the obvious remedy is the ingestion of food; it may then be necessary to take meals at more frequent intervals than in health, or to relieve the uneasiness in these intervals by taking a biscuit or some other light and easily digested refreshment. It not unfrequently happens that persons otherwise healthy, who have nothing after their dinner at five, six, or seven o'clock, wake in the middle of the night with gastralgia,

or complain of similar pain with nausea and perhaps sickness in the morning. The proper treatment for such cases is the taking either of a light supper before going to bed or of a light meal before rising in the morning. When pain occurs immediately after the ingestion of food it implies the presence of morbid irritability, inflammation, or organic mischief in the walls of the stomach, and may be treated partly by regulation and selection of diet, and partly by the use of drugs, such as nitrate of silver, hydrocyanic acid, or bismuth, given before food. If the pain be dependent on flatulent distension, peppermint, ginger, and other carminatives are generally useful. Mineral acids, and the earthy or alkaline carbonates, are often valuable in relieving pain, as they are in relieving other dyspeptic symptoms. It is not always easy to determine *à priori* which remedies are best suited for any particular case. It, may, however, be assumed, as a general rule, that when the secretions of the stomach are alkaline or neutral, as they are apt to be in inflammatory conditions, acids are indicated; that when they are acid, alkalies, if not specially indicated, are at all events more suitable. Opium is of great value in the relief of gastric pain, and may frequently be advantageously combined with other remedial agents, especially perhaps bismuth or kino. When the gastralgia is severe, and especially if it be of a spasmodic character, and associated with faintness or collapse, opium may be regarded as our sheet anchor. It should be given in large and, if necessary, repeated doses. Blisters and other counter-irritants, or fomentations, to the epigastric region, are often useful.

For *flatulence and eructation*, carminatives, and more especially the essential oils, some of the oleo- or gum-resins, ammonia, or brandy in small quantities, are generally beneficial; but they are beneficial rather by assuaging present uneasiness and dispersing wind by eructation than by any direct curative influence. For relieving these conditions, however, as well as for checking vomiting, careful attention must always be paid to the quality, quantity, and times of administration of food.

*Nausea and vomiting* may be benefited by various agents: by ice in small quantities; by the alkaline carbonates, which may often be advantageously given in an effervescing form with lemon-juice or citric or tartaric acid; by oxalate of cerium, carbonate of magnesia, lime-water, bismuth, nitrate or oxide of silver, hydrocyanic acid, or creasote. When flatulence, eructation, and vomiting are dependent on, or associated with, fermentation or putrefaction of the contents of the stomach, special treatment may be called for: fermentation may be checked by the use of creasote, sulphite of soda, or sulphurous acid; putrefaction by the exhibition of the mineral acids and more especially hydrochloric acid, with which pepsine may be combined.

In pyrosis or water-brash the above forms of treatment may be serviceable, but generally bismuth alone or combined with opium, or the vegetable astringents conjoined with a narcotic (the compound kino powder, for example), appear to have a special value. In cases in which the stomach is excessively dilated it is often useful to empty the organ

from time to time by means of the stomach-pump, and then to wash it out.

Lastly, it must never be forgotten that in all cases of chronic dyspepsia hygienic treatment, inclusive of moderate exercise, regulated hours, well-ventilated rooms, and change of air and scene, is of considerable importance.

## XX. DIARRHŒA

The term diarrhœa, like the term dyspepsia, is applied to a symptom or group of symptoms common to a wide range of morbid conditions, of which the majority are discussed in various parts of this volume. It is needless, therefore, as well as inappropriate, to enter upon the subject here at any great length.

*Causation.*—Diarrhœa is of common occurrence at some period or other in the course of many febrile or other constitutional maladies. It not unfrequently complicates hepatic and splenic disease, and other affections which induce undue congestion of the portal vessels and their tributaries. It is one of the ordinary consequences of organic lesions, of whatever kind, of the mucous membrane of the bowels. It is frequently induced by inflammatory conditions of the same tract, by the ingestion of unwholesome or irritating articles of food, or by over-eating. It is certain, also: that it is sometimes caused by nervous influences, and especially by anxiety, fear, and allied mental emotions; and that excessive or perverted secretion from the alimentary canal, or from the glands which open into it, has a large share in its production. Among circumstances which exert an important influence in causing diarrhœa are age, habits, and season, with other climatic conditions. Thus it is peculiarly frequent amongst young children, especially at or about the times of weaning and teething; again, it, or its converse—constipation—is very apt to follow upon dietetic and other changes of habit; and further, the influence of hot weather, and especially in this country of the later summer months, and of alternations of temperature, in its causation is well known.

In considering the pathology of diarrhœa, we shall first discuss the influence of the contents of the gastro-intestinal canal in its causation. It is the presence of alimentary matters which, in conjunction with that of the normal secretions, excites those peristaltic movements which terminate with defæcation. The bowels as well as the stomach are no doubt in many cases very long-suffering; yet, notwithstanding this, they are frequently stimulated to unwonted action by the matters which gain entrance into them. Excess of even wholesome food, the ingestion of difficultly digestible or unwholesome matters, the use of polluted water, even the transmission from the stomach of imperfectly reduced contents, or of such as are undergoing fermentation or putrefaction, are all likely to cause intestinal disturbance, with consecutive diarrhœa. Again, excessive discharges from the liver or intestinal surface, especially if they assume an inflammatory character, do, even when themselves determined

by the influence of irritating alimentary matters, materially promote the abnormal action of the bowels. Amongst causes of intestinal irritation must also be included prolonged constipation, or excessive accumulation of fæces.

Of the important part the mucous surface of the bowels plays in relation to diarrhœa there is no room for doubt. It is, in fact, by the influence of the contents on this surface that they are themselves influential in causing it. The conditions of the mucous membrane which promote diarrhœa are (omitting morbid growths, degenerative changes, and other destructive lesions) irritability, irritation, and catarrhal inflammation. In the first case, the over-sensitive surface resents the contact of the normal intestinal contents, and excites the muscular walls to propel them rapidly onwards; in the second, the healthy intestinal walls are excited to unwonted action and over-secretion by the irritating matters which are in contact with them; in the last there is actual inflammation present, with more or less important change in the character and quantity of the secreted juices.

Without the action of the intestinal muscular walls, diarrhœa could not exist; it is owing indeed to their powerful and frequently recurring peristaltic movements, for the most part reflectorally excited from the mucous surface, that the contents of the bowels are carried onwards with unwonted energy. But their action is under the immediate direction of the sympathetic nerves, and it is quite possible (as has been proved experimentally) for energetic peristalsis to be excited by the direct irritation of these nerves, and hence for similar movements to be induced through their agency by causes originating in the central nervous organs or other remote sources of irritation. Trousseau, indeed, refers one form of diarrhœa, as well as one form of dyspepsia which is commonly associated with it, to increased tonicity of the intestinal and gastric muscles—a condition which, if it exist, is evidently dependent on nervous agency. The influence of depressing passions in causing diarrhœa is exerted obviously through the nervous system; but whether this operates by simply augmenting peristaltic movement, or in the first instance promoting excessive flow of mucus and other fluids into the intestinal canal, is a question which it would be somewhat difficult to decide.

*Symptoms and progress.*—By diarrhœa we mean strictly the actual discharge from the anus of unformed or fluid motions in greater quantity or more frequently than natural. But owing to the remarkable length of the alimentary canal, and to variations in its structure and functions in different parts of its course, we may have conditions which correspond essentially to diarrhœa developed at different parts and leading to different results. Thus if the affection involve the large intestine, diarrhœa (dysenteric in character) will certainly ensue; if, however, it attack the upper part of the jejunum, the diarrhœa (so to speak) may only occur between the jejunum and the ileum, or between these and the cæcum: the patient will suffer from colic or griping, but instead of frequent loose evacuations there may be actual constipation.

As regards the characters of the alvine discharges, there will necessarily be much variety, dependent partly on the nature of the ingesta, partly on the amount and quality of the secretions of the different glandular organs, partly on the fermentative and other changes which take place in the bowel, and partly on the rapidity with which the contents of the stomach are carried onwards to the anal orifice. We may discover in the evacuations solid masses of animal or vegetable matter, fat which has not been saponified, comparatively large quantities of only slightly modified starch, and, in young infants, coagulated but otherwise scarcely altered milk. They may contain large quantities of mucus, unmixed if it be secreted by the large intestine, incorporated and imparting pallor and fluidity if it be furnished by the remoter portions of the bowel. Or the discharges may be exceedingly copious and almost watery in character, and may contain either large quantities or mere traces of biliary colouring matter. Fluidity of the evacuations may be due in large measure to simple hurry in the transmission of the contents of the bowels, and to the consequent escape with the fæces of those natural secretions which under normal circumstances would have been reabsorbed; there is no doubt, however, that in a large number of cases it is dependent in a greater or less degree on excessive secretion. When fermentation or decomposition occurs, there is, attending the diarrhœa, much discharge of flatus, which is often exceedingly offensive; and the evacuations, which are watery and fetid, present a frothy or yeast-like character. Under these circumstances the yeast-fungus or the *sarcina ventriculi* may generally be discovered in them. When the contents are propelled along the intestinal canal with great rapidity, there is insufficient time for digestion, at all events for intestinal digestion, to be efficiently performed; and it is under such circumstances that the condition termed *lientery*, or the passage of undigested food, frequently takes place. We may here call attention to the fact that ovarian and other cysts, hydatid tumours and abscesses, may open into the bowel and give rise to diarrhœal stools, of which their contents form an important and often obvious constituent.

The essential symptoms of diarrhœa are pain and the occurrence of loose stools; but with these are usually associated others of more or less severity and importance. Pain of an aching, griping, or colicky character is generally present, coming on at intervals, attended with borborygmi and manifest movements of the bowel, and varying in its seat. It differs in severity, and is sometimes so intense that the patient rolls about or writhes in agony, and a state of partial collapse, with coldness of surface, perspirations, and feeble pulse, is induced. If it be developed high up in the course of the bowel, vomiting not unfrequently takes place; if it occur in the lower part of the large intestine, spasmodic expulsive actions of the abdominal muscles are excited. There is not usually abdominal tenderness; the pain, indeed, is often relieved by pressure or friction. In some cases of diarrhœa, copious evacuations take place with little or no uneasiness or pain. The different characters of the stools have already been detailed. It remains to say: that the quantities discharged vary within

wide limits, and are sometimes as enormous as they are in cases of epidemic cholera; and that the frequency of the evacuations presents equal variety. Among the associated symptoms, which may or may not be present, are dryness or coating of the tongue, soreness of the mouth and fauces, anorexia and thirst, nausea, vomiting and eructation, giddiness, headache, and, as has already been stated, symptoms of faintness or collapse, sometimes alternating with flushes of heat and slight febrile disturbance. When diarrhœa is profuse, and at the same time chronic, innutrition with emaciation and loss of strength ensues; and death may ultimately result either from simple exhaustion or from the supervention of complications.

It is scarcely necessary to specify in detail the different characteristic features of the many various forms of diarrhœa which are met with in practice, or to insist on the extreme difficulty and frequent impossibility of distinguishing functional diarrhœa, which is now under consideration, from the diarrhœa of intestinal lesions. There are two forms of diarrhœa, however, which call for particular remark, namely, *infantile diarrhœa*, and *summer (English) cholera*. Although receiving different names it would be difficult to draw any clear line of distinction between the morbid conditions here associated. We shall, therefore, combine their description. Infants, especially at or about the time of weaning, are remarkably apt to be attacked with diarrhœa, and to fall victims to it; and this tendency is greatly increased during the summer months, when diarrhœal complaints are common not only in children but in adults. The attack, whether in the infant or the adult, sometimes comes on suddenly, sometimes supervenes in the course of some slight gastro-intestinal disturbance. It usually commences with copious and repeated vomiting, first of the normal contents of the stomach, then of watery fluid, containing bile. The diarrhœa is at first characterised by the expulsion of the contents of the lower bowel but little altered; but gradually the evacuations become more and more thin and watery, though still tinged and not unfrequently green with biliary colouring matter. With these phenomena are associated intense thirst, much pain and griping in the belly, which is usually retracted, and cramps in the limbs, together with collapse, indicated by coldness of surface, rapidity and feebleness of pulse, pinched features, sunken eyes surrounded by dark circles, bluish finger-nails, sighing respiration, altered voice, and restlessness. The symptoms have, in fact, a close resemblance to those of Asiatic cholera, but differ from them clinically in the circumstances: that the evacuations rarely if ever assume the rice-water character, or are devoid of bile; that the urine is not generally suppressed; and that the collapse is neither so sudden nor so extreme as that of the epidemic disease. Nevertheless the affection is very dangerous, carrying off a large proportion of the children whom it attacks, and not unfrequently proving fatal to adults. If recovery take place from the stage of collapse a febrile stage ensues in which the temperature rises, the surface assumes a normal or febrile aspect, the tongue gets red and dry, and the evacuations (which probably remain diarrhœal) acquire something of a

dysenteric character. The patient becomes dull and lethargic, and, if a child, falls into a condition of stupor, with moaning plaintive cries, and jactitation, which may readily be mistaken for symptoms of cerebral disease. The period of collapse lasts from a few hours to twenty-four or thirty-six hours; and it is especially during this period that death is likely to occur. The later stage may be continued for several days or for a week or two.

*Treatment.*—The treatment of diarrhœa must depend mainly upon the causes to which it is due and the symptoms with which it is attended. When it is distinctly the consequence of alimentary errors, it is usually best at the commencement to aid the removal of offending matters either by emetics, such as mustard and water or a full dose of ipecacuanha, or by purgative medicines, such as hyd. c. cretâ, blue pill, Gregory's powder, compound rhubarb pill, an ordinary black draught, or castor-oil. Such measures may effect a cure; but, if the diarrhœa still persist, carminatives and astringents may be requisite. Of these compound kino powder, aromatic chalk and opium, chalk mixture, or lime-water or bismuth combined with vegetable astringents, opium or rhubarb, may be efficacious. If these fail recourse may be had, according to circumstances, to tannic acid, lead and opium, copper, perchloride of iron, nitrate of silver, or sulphuric acid. An essential element in the treatment, however, and one which is alone often sufficient for the purpose, is partial or complete abstinence from food for a time, and subsequent limitation of the patient's dietary to such matters as are bland and easily digestible. Milk, arrow-root, and such-like substances, broths, toast, and simple well-baked biscuits, are especially suitable. In the case of young children no purgative medicines probably are better than chalk and mercury, Gregory's powder, or castor-oil; and no combination of astringents and aromatics better than aromatic chalk and opium or small quantities of catechu, opium, aromatic chalk, and syrup of ginger in solution. In this case, too, especial attention must be paid to diet. If the child has been weaned it may be necessary to supply it again from the breast; or to provide it with asses' or goats' milk; or to feed it with skimmed cows' milk to which lime-water may be added, or with well-baked flour or suitable biscuit powder diffused or suspended in water or milk. If the diarrhœa be of distinctly inflammatory origin, very much the same kind of treatment is needed; purgatives may still be requisite in the early stages, but castor-oil or salines are probably to be preferred. Dietetic treatment also in these cases is of great importance. If there be much abdominal uneasiness or griping, warm fomentations or mustard plasters to the parietes, or the warm bath, may be beneficial.

In the choleraic form of diarrhœa, which attacks young children and adults mainly in the summer time, little or nothing can be done at first to arrest the diarrhœal phenomena. Trousseau regards the mustard bath (made by enclosing a cold paste of mustard in a muslin bag and squeezing this in the water of the warm bath until the latter is sufficiently impregnated) as the most powerful and efficacious remedy; and directs that it should be employed for about a quarter of an hour, or until the mustard causes some

tingling of the surface, and that it should be repeated if necessary. For internal treatment the exhibition of iced water, rice-water, decoction of barley, skimmed milk, or the *eau albumineuse* of Trousseau (made by diluting the whites of four eggs with about  $1\frac{3}{4}$  pints of water, sweetened with sugar and flavoured with orange-flower water) may be resorted to with advantage. During the same period emetic doses of ipecacuanha, and purgative doses of the hyd. c. cretá, are of common use and strongly recommended; but if the collapse be serious, diffusible stimulants, such as ether and ammonia, or some form of alcoholic beverage, is demanded. At this period opium is a remedy of questionable efficacy, and in the case of young children should be carefully avoided. With the cessation of diarrhœa and vomiting and the supervention of febrile symptoms the diet above recommended must still be continued, but the medicinal treatment must now be that which is beneficial in catarrhal inflammation of the bowels, and may include such drugs as bismuth, chalk, and lime-water, with opium.

Chronic diarrhœa is often very intractable, and requires much judicious management for its successful treatment. Hence attention to diet is of supreme importance. It is impossible, however, to lay down any definite rules in reference thereto. In many cases fluid nutriment is most suitable; in some food is best administered in the solid form; in some the farinacea agree best, in some alimentary matters derived from the animal kingdom. We must be guided in each case, partly by the patient's own feelings and experience, partly by the special symptoms present and the character of the evacuations, and partly, of course, by the opinion which we form of the nature and origin of the attack. In such cases it not unfrequently happens that the diarrhœa is kept up by the habitual use of some unsuitable article of diet, or by the constant presence of some hygienic condition inimical to the patient's health, or by the continued indulgence in habits which are injurious to him. It is in chronic diarrhœa (especially in children) that the use of raw meat to the exclusion of all other food has been so strongly advocated. The lean of beef or mutton should be selected, minced, pounded in a mortar, squeezed through a sieve, and given either in the form of the simple pulp, or mingled with sugar, red-currant jelly, or other similar substances. It should be administered at first in small doses, and then gradually increased. Trousseau has thus given as much as a pound a day to a child less than three years old. We must not forget the danger which in taking raw meat our patient incurs of becoming affected with tœnia—a danger which both Trousseau and Goodeve have shown not to be fanciful. For medicinal treatment we may have recourse to the various vegetable astringents and bitters, or to bismuth, silver, copper, or iron, or to the mineral acids, or to rhubarb or ipecacuanha, or to opium, nor must we forget the benefit which may result from the occasional administration of saline or stomachic purgatives.

## SECTION IV.—DISEASES OF THE LIVER AND PANCREAS

## I. INTRODUCTORY REMARKS

*A. Anatomical Relations*

In investigating hepatic diseases, a careful examination of the hepatic region should not be neglected. The healthy liver occupies the right hypochondrium, extending across the scrobiculus cordis into the left hypochondrium; and throughout this extent is accurately adapted to the vault of the diaphragm. In the recumbent posture the lower edge is usually concealed by the lower margin of the right side of the chest, except in the upper part of the epigastric region, where small portions of the right and left lobes lie uncovered. The position of this edge varies, however, during respiration—descending somewhat in inspiration, ascending again in expiration; it descends also to a slight extent when the sitting or upright posture is assumed. Moreover, in women who lace tightly, and occasionally in other healthy persons, it may be found as much as two or three inches below the margin of the ribs. In some cases, on the other hand, it occupies normally a higher position than usual. The upper limit of the liver necessarily corresponds to the position of the diaphragm with which it is in contact, and is higher, therefore, on the right than on the left side. The upper margin, however, of that area of its upper surface which has only the diaphragm and thoracic walls in front of it occupies a lower level, corresponds to the lower and outer margin of the right lung, and varies with the varying positions of that margin. Adopting Frerichs's estimates, it may be assumed that (liable to more or less variation); in the nipple line, the true upper boundary of the liver corresponds to the fifth interspace, the line of separation between the edge of the lung and the liver to the sixth rib; in the axillary line, the former to the seventh interspace, the latter to the eighth rib; and near the vertebral column, the former to the tenth interspace, the latter to the eleventh rib. All that region to which the liver is immediately subjacent is dull or nearly so on percussion; and in front and to the left the upper part of that region merges in the cardiac area, and below and behind in that of the right kidney. General increase in the bulk of the liver is attended both by the ascent of the upper margin of the hepatic area into the chest, and by the descent of its lower margin into the abdomen—the latter being necessarily the more considerable. The lower margin then can generally be well distinguished, with all its characteristic peculiarities of outline. In some cases it descends into the iliac and hypogastric regions. When, however, the enlargement of the liver is irregular, or due to the presence of tumours, in some cases its extension is wholly at the expense of the thoracic cavity, and the walls of the lower part of the right side of the chest may be distinctly protruded over it; in other cases its extension takes place mainly downwards, and the irregularity of form of the affected organ may then be readily distinguished though the abdominal walls. When

the liver diminishes in size its area of dulness shrinks correspondingly, and sometimes wholly disappears. Occasionally, moreover, under these and other circumstances, the intestines rise up and intervene between the liver and parietes.

### *B. Physiological Considerations*

In entering upon the subject of the diseases of the liver, it is important that we should have some preliminary acquaintance with the nature of the functions which this organ has to perform, and on the disturbance or modification of which many of the more important or striking phenomena of hepatic disease necessarily depend. In the brief review of this subject, which we are now about to place before the reader, we shall avail ourselves largely of the masterly summary given by Dr. Murchison in his work on the functional derangements of the liver.

The liver appears to have at least three important and more or less distinct offices to fulfil. First, starchy and saccharine matters, brought to it by the portal vessels from the alimentary canal, are converted by it into glycogen ( $C_6H_{10}O_5$ ), a substance resembling dextrine, and convertible, like it, into sugar by the action of albuminoid ferments. Glycogen is formed and stored in the hepatic cells, whence (especially during the intervals of fasting) it is removed in the form of sugar by the hepatic veins, and then distributed; partly, for the maintenance of heat, to be converted by the respired oxygen into carbonic acid and water; partly to take an important share in the growth, development, and functional activity of cells, and probably even in the development of the white corpuscles of the blood. Further, glycogen is probably convertible into fat, and, under certain circumstances, the source of accumulation of oil in the hepatic cells, or of adipose deposition in other parts of the body. Second, albuminous matters, whether derived directly from the food, or constituting an essential part of the blood, and especially fibrine, appear to become reduced, through the agency of the liver, into various simpler compounds. These include glycogen, the destination of which has already been considered, and effete matters, such as leucine ( $C_6H_{13}NO_2$ ) and tyrosine ( $C_9H_{11}NO_3$ ), which are ultimately resolved into uric acid ( $C_5H_4N_4O_3$ ), and more particularly into urea ( $CH_4N_2O_2$ ), and then discharged with the urine. Urea itself appears, at all events to some extent, to be manufactured in the liver. Third, the liver secretes bile. This is a thin, transparent, golden-yellow fluid, which gets viscid and assumes a darker colour in the gall-bladder in consequence of its admixture with mucus. Roughly speaking, about two pints of bile are secreted daily by a healthy adult, of which from 9 to 17 parts per cent. consist of solid matters. These comprise small though varying proportions of mucus, fat, salts, and compounds due to the disintegration of albuminous substances, but mainly certain ingredients of special interest and importance, namely resinous acids in combination with soda, colouring matter, and cholesterine. The resinous acids, which are two in number, are the glycocholic and the taurocholic; they are both conjugate acids, the former being formed by the union of glycocholl ( $C_2H_5NO_2$ ) with cholic acid

( $C_{24}H_{40}O_5$ ), the latter by the union of taurine ( $C_2H_7NO_3S$ ) with cholic acid. The latter acid contains all the sulphur of the bile, and to it the bitterness of this fluid is due. The peculiar colour of bile is owing to the presence of a pigment now termed bilirubine ( $C_{16}H_{18}N_2O_3$ ). This readily undergoes oxidation even in the gall-bladder, becoming successively yellow, green, brown, and black. Bilirubine crystallises in ruby-coloured, rhomboidal crystals, which are scarcely, if at all, distinguishable from hæmatoidine crystals, but chemically are said to contain one atom more of carbon. Cholesterine forms a small but constant part of the solid constituents of the bile, and is usually the main constituent of biliary calculi. As regards the sources of the essential ingredients of the bile, it has been maintained by some that they are, like urea, formed in the blood, and simply separated from it by the liver; by others that they are a product of that disintegrating power which the liver itself has over the albuminous and other matters which are brought within its influence. The latter view is now generally accepted. Taurocholic and glycocholic acids appear, therefore, to be products of that disintegration of albuminous substances to which reference has already been made; and bilirubine to be a derivative of the colouring matter furnished by disintegrating blood-corpuscles. It has been suggested by Dr. Austin Flint, jun., that the cholesterine of the bile is to be traced to the disintegration of nervous tissue, and that one of the chief functions of the liver is the separation of this fatty matter from the blood. The purpose and destination of the bile have been equally a matter of dispute. There is little doubt, however, that the bile is an important agent in the saponification and absorption of fats, and even in the assimilation of albuminous matters, and further, that it promotes peristaltic action, and arrests decomposition. It is certain that it is only in some small degree excrementitious, the great bulk of it, like saliva and gastric juice, being reabsorbed, in a more or less modified condition, into the system. The excrementitious parts comprise portions of the colouring matter and of cholic acid, and certain derivatives of cholesterine. The parts which are reabsorbed comprise the taurine, the glycocoll, the greater part of the cholic acid, and a considerable proportion of the colouring matter; which last, there is reason to believe, becomes converted into the pigment of the urine.

### *C. Pathological Considerations*

It will be readily understood from the above observations how numerous and various are the ways in which diseases of the liver may affect the nutritive and other processes of the body, and how numerous and various are the symptoms to which they may give rise. Diabetes has long been regarded as a functional affection of the liver; and Dr. Murchison attributes to functional disturbance of this organ not only gout, renal calculi, and biliary calculi, but a large proportion of the functional and structural derangements of nearly all the organs and tissues of the body. The most striking, if not the most important, results, however, of hepatic diseases are those connected with derangement or suppression of the biliary secretion

—namely, jaundice and various associated phenomena, which will presently be fully considered.

A further consequence of structural disease of the liver, or of any disease implicating the trunk of the portal vein, is impediment to the ready flow of blood through this vessel or through its branches of distribution to the liver, and hyperæmia of the tributary vessels connected with the other chylipoietic viscera. This hyperæmia leads to various mechanical consequences, especially to permanent dilatation of the vessels which when occurring in the vicinity of the anus constitutes hæmorrhoids; to more or less profuse hemorrhage from the mucous surface of the alimentary canal; and to abdominal dropsy.

*Jaundice.*—This is due to the circulation with the blood, the deposition in various tissues, and the separation, through the agency of certain unwanted emunctories, of the colouring matter of the bile, and its various modifications. But, as we have pointed out, the bile contains other ingredients besides colouring matter, and the hepatic cells have other functions to perform besides the mere manufacture of bile. It is obvious, therefore, that the existence of jaundice (the circulation of biliary colouring matter) almost necessarily involves the circulation of other ingredients of the bile which are less readily detected, and probably also the presence in the blood in greater or less abundance of various effete derivatives of albuminous matters.

But what is the explanation of the accumulation of biliary colouring matter in the blood? By those who hold that the liver excretes bilirubine and the other constituents of the bile exactly as the kidney excretes urea, jaundice is attributed to loss or diminution on the part of the liver of its dialysing power. There is ample evidence, however, from the results of removal of the liver in the lower animals, that bile is not formed in the blood, and that as a general rule the presence of the liver is essential to the production of jaundice. It is certain also that when jaundice follows the experimental obstruction of the hepatic ducts, it first manifests itself in the hepatic cells and then in the lymphatic vessels which take their origin in the liver—facts which clearly demonstrate that in this case at all events the jaundice is due to the passage into the general circulation of colouring matters manufactured in the liver. It has hence been assumed, and doubtless with truth, that in those cases in which jaundice is due to obstruction, the colouring matter of the bile formed in the cells is absorbed both from the cells and from the hepatic ducts behind the seat of obstruction, by the hepatic venous capillaries and lymphatics, and thus becomes distributed throughout the system. It has also been assumed, but on a far less substantial basis, both by Frerichs and by Murchison, that jaundice may arise, in cases of prolonged constipation and in cases of excessive secretion of bile, from absorption taking place at the mucous surface of the bowel.

But if the hepatic cells are in a condition to manufacture bilirubine, they are doubtless also in a condition to manufacture the biliary acids. What, then, becomes of these? They are absorbed, together with biliary

colouring matter, and mingle with the circulation, but what becomes of them further is still a matter of dispute. Dr. G. Harley and others assert that they accumulate in the blood, and are discharged with the urine, in which fluid they may be detected by appropriate means. Frerichs, on the other hand, and Dr. Murchison agrees with him, believes not only that they are never found in the urine, but that in the blood they speedily undergo chemical changes, and their identity becomes lost. Frerichs also holds that the reabsorbed biliary acids may be converted into biliary pigment, and that hence their absorption may increase jaundice if it do not absolutely create it.

But, even if it be admitted that the above explanation holds good of all those cases in which jaundice is due to obstruction of the hepatic ducts, and that it may be extended to cases of jaundice (if there be such) referrible to intestinal obstruction, or to excessive production of bile, it is clearly inapplicable to some, at all events, of those cases in which (as in pyæmia and certain infectious fevers) jaundice is an item of a general disease, and to the cases in which (as probably in malignant jaundice) the icteric tinge is associated with the destruction of the secreting cells of the liver, and their consequent inability to discharge their specific functions. The close relationship of the colouring matter of the blood to that of the bile, and the fact that the one is derived from the other, and both yield parallel series of almost identical coloured derivatives, make the view which Virchow strongly advocates (namely, that in many of the latter cases jaundice is due, not to the agency of the liver, but to changes in the hæmatine effected in the general circulation) both highly probable and easy of acceptance. Frerichs, however, even in reference to some of these cases, prefers to believe that the jaundice is attributable to the absorption of the elements of bile at the mucous surface of the bowel and to interference with the due course of those changes which the reabsorbed bile should undergo in the blood. It is important to add: that when, as in malignant jaundice, the secreting structure of the liver is destroyed, the jaundice is not usually intense, and the biliary acids are certainly never detected in the urine, while, on the other hand, the retrograde metamorphosis of albuminous matters remains incomplete, and leucine and tyrosine, which accumulate in the blood, replace more or less completely urea in the urine; and that, according to Dr. G. Harley, Kühne, and others, when jaundice is the result of obstruction, the biliary acids may be recognised in the urine, and that their recognition there may be taken as proof of the obstructive origin of the jaundice.

The phenomena which attend and indicate jaundice, and the consequences which flow from it, are various, but the more important of them may be readily enumerated.

1. There is usually deficiency of bile in the alvine discharges, and consequent tendency to constipation, flatulence, fætor of the evacuations, faulty assimilation, especially of fat, and distaste for fat. If the bile be wholly absent, these phenomena are more strongly marked, and the fæces acquire a chalky, grey or slaty colour, or assume some tint referrible to the pre-

vailing character of the patient's diet. Diarrhœa sometimes comes on ; and fatty matters, but little altered, are apt to pass away with the evacuations.

2. Omitting for the present all reference to the changes taking place in the liver itself, the colouring matter of the bile first accumulates in the blood, then escapes with the urine, and subsequently gradually tinges the conjunctivæ and skin, passing off at the same time in some small degree with the sweat. Other parts which become bile-stained are the serous membranes and all effusions which take place in connection with them, the connective and fibrous tissues, fat, muscles, and bones. The mucous membranes as a rule are scarcely affected ; and the secretions from their surfaces and from the glands which open upon them are usually entirely free. The brain and nerves remain for the most part uncoloured. The only secretions besides those of the kidneys and sudoriparous glands, which have certainly been found to contain bile, are that of the mammary gland and those furnished by *inflamed* mucous surfaces. Superficial jaundice first shows itself in the conjunctivæ, but soon becomes generally diffused throughout the whole cutaneous surface. It is at first a mere condition of sallowness, but soon assumes a saffron or golden-yellow hue, and, if long continued, a brownish, olive, or bronze-like tint. The seat of discolouration is mainly the rete mucosum and the sudoriparous glands. The secretion of the latter, indeed, sometimes becomes so largely charged with bile-pigment as to stain the linen. The usual characteristics of bilious urine, and the tests for the recognition of bile-pigment in that fluid, are elsewhere considered. It may, however, be pointed out here that the urine varies in colour from a saffron-yellow to a greenish or brownish black, that its froth always presents a peculiarly yellow hue, that it stains white paper and linen, and further, that it is generally free from sediment, transparent, and acid. It is apt, however, to present other peculiarities of which some have been already adverted to ; it occasionally yields uratic or other deposits ; it may possibly, when the jaundice is obstructive, contain bile-acids ; it certainly displays, in the presence of extensive destruction of the hepatic cells, a remarkable diminution of urea and of phosphates, and in their place a great abundance of leucine and tyrosine, which then sometimes fall as a greenish-yellow sediment ; and lastly, there is often, especially towards the fatal close, either glycosuria or albuminuria, or both. Albuminuria is probably connected with the irritation caused by the long-continued passage of bile-pigment. All the tissues of the kidneys, and more especially the cells of the convoluted and straight tubes, gradually get deeply stained ; and the canals of the tubes are not unfrequently occupied by granular or amorphous pigmented casts which become shed and may be found in the urine.

3. There are several other phenomena occasionally associated with jaundice, of which some are interesting, others are of grave importance. It is asserted that sometimes all objects appear yellow to jaundiced patients. But this occurrence is rare, and the explanations which have been given of it are conflicting. There is often troublesome, and some-

times unbearable, itching of the skin. This is not generally attended with obvious eruption; but occasionally we find lichen, urticaria, or some one of the different varieties of erythema multiforme. Vitiligoidea or xanthoma is well known to be frequently associated with chronic jaundice. The action of the heart is usually much enfeebled, and often reduced in frequency; there is also a marked tendency to the occurrence of hemorrhage, revealing itself by the appearance of petechiæ, or by epistaxis or gastro-intestinal or other fluxes, which may be so copious, or so frequently repeated, as to prove fatal. Together with these symptoms, the patient usually becomes emaciated and feeble, irritable or low-spirited, and little capable of resisting the influence of either mental or bodily fatigue or changes of weather.

It is not surprising that patients suffering from jaundice should sooner or later present impairment of nutrition and other indications of profound ill-health. It is surprising rather that they should live as long as they occasionally do, and yet present so few symptoms and undergo so little suffering; and that bile itself should, as has been shown by experiment, have so little injurious influence over the blood and the various corporeal functions. But occasionally symptoms of so-called 'bilious toxæmia' arise. They seem, however, to occur mainly, if not solely, in those cases in which jaundice is connected with destruction of the hepatic cells, in which urea tends to disappear from the urine, and leucine, tyrosine, and other products of albuminous decomposition circulate with the blood and find their way into the urine. And, indeed, the toxæmic effects seem to be due, not to the influence of the proper elements of bile, but to that of various excrementitious matters, of which leucine and tyrosine are probably the most important. The symptoms here referred to comprise: in the first instance, headache, restlessness, mental depression or excitement, and sense of illness; then busy or violent delirium, or convulsions, varying from mere rigors to general epileptiform attacks or tetanic spasms, or delirium and convulsions intermingled; and finally stupor, passing into coma and death.

---

## II. INFLAMMATION OF THE HEPATIC DUCTS

*Causation.*—Inflammation of the biliary ducts and of the gall-bladder may be due to the presence of gravel or calculi, or to the extension of inflammation from the parenchyma of the liver. These subjects will be considered hereafter. But inflammation affecting mainly the mucous surface, and catarrhal in character, frequently arises from exposure to vicissitudes of weather, or from gastro-intestinal disturbance, and perhaps also in connection with pneumonic and other acute inflammations, and various infectious fevers. It is most frequently preceded by a similar affection of the duodenum.

*Morbid anatomy.*—Catarrhal inflammation is generally indicated by an excessive discharge of ropy mucus, and by swelling of the mucous membrane; and these phenomena not unfrequently lead to more or less complete obstruction. This usually occurs in the common duct, and especially in that part of it which is embraced by the intestinal walls. It is generally temporary, subsiding in the course of two or three weeks or less, but sometimes results in organic stricture, sometimes in permanent closure, or in closure which is relieved only by the supervention of ulcerative destruction. In some instances a false membrane forms upon the mucous surface, and occasionally polypi or papillary growths are developed. The most remarkable consequences of catarrhal inflammation are those which depend immediately on mechanical impediment to the escape of bile, and which therefore are associated from the beginning with mechanical distension of the ducts. These are suppuration, hemorrhage, ulceration, and more or less extensive destruction of the mucous membrane.

*Symptoms and progress.*—The early symptoms of catarrhal inflammation of the gall-ducts, which are usually undistinguishable from those of the gastro-intestinal catarrh wherewith they are associated, are mainly flatulence, distension, weight and pain in the region of the stomach, nausea and vomiting, and for the most part constipation, together with slight febrile disturbance. The proof of implication of the hepatic ducts is furnished after the affection has lasted for several days, possibly a week or two, by the coming on of jaundice with some degree of tenderness and enlargement of the liver. In many cases the symptoms preliminary to jaundice are so vague and slightly developed that they escape observation; and not unfrequently they subside shortly after the supervention of jaundice. The jaundice itself, however, with constipation and other results of retention of bile, usually continues for a week or two, or a little longer. Catarrhal inflammation almost always ends in resolution within the period above assigned. Sometimes, however, it becomes chronic, and may then continue for months with the combined symptoms of gastro-intestinal irritation and retention of bile, the patient probably becoming feeble and emaciated. The consequences of permanent stricture, or of complete impediment to the escape of bile, will be considered under the head of 'Obstruction of the Hepatic Ducts.'

*Treatment.*—In treating the affection under consideration, febrifuge or alkaline medicines, and saline purgatives, or mild laxatives of other kinds, are generally indicated. Food of an unstimulating character, for the most part farinaceous substances and milk, should be administered. And local pains or uneasiness should be counteracted by hot fomentations or counter-irritants. Leeches or cupping is rarely if ever necessary. It is often well to have recourse to those remedies which have a special influence over the morbid conditions of the gastro-intestinal mucous membrane, and especially to stomachic combinations, such as mixtures of soda, potash, or bismuth with rhubarb, ginger, and some bitter infusion. Emetics also have been strongly recommended in the early stages of the

disease, with the object mainly of promoting the flow of bile along the obstructed tubes, or of effecting the dislodgment of the plugs of mucus which it is assumed may be impacted in them.

### III. ACUTE HEPATITIS. ABSCESS OF THE LIVER

*Causation.*—Acute inflammation arises under various circumstances. It may be due to injury; to the irritation of adventitious growths or hydatids; to extension of inflammation from the ducts or veins, or from without; to pyæmia, whether taking its origin in ulceration of the bowel or from some more remote source; to pre-existing congestion of the organ, especially in connection with heart-disease; to the influence of acute inflammations, such as erysipelas and pneumonia, or of the specific fevers, such as yellow-fever, small-pox, and scarlatina; to the toxic effects of phosphorus and certain metallic poisons; and lastly, it is not unfrequently of idiopathic origin, mainly, however, in tropical climates and in connection with dysentery. The nature of the relation between dysentery and hepatic abscess has already been discussed under the head of ‘Dysentery.’

*Morbid anatomy.*—Inflammation of the liver, as of other organs, affects mainly the connective tissue and the small vessels in the meshes of which the proper elements of the gland are contained. The vessels become dilated and full of blood with a superabundance of leucocytes; the tissues get infiltrated with inflammatory exudation; and a development of embryonic tissue takes place in the walls of the small vessels and ducts, and their immediate vicinity, in Glisson’s capsule, and generally in the connective tissue. At the same time the proper cells of the liver become swollen and cloudy, and even the seat of fatty or pigmental deposition, and are sometimes destroyed. The appearances presented by the inflamed tissues differ widely in different cases, in dependence mainly on the causes to which the inflammation is due and on its intensity. In some cases the most marked features are uniform opacity and lightness of tint, with doughiness of consistence, and enlargement of the lobules. These peculiarities are due to the fact that the hepatic cells have become cloudy and swollen; while, in some measure, owing to this very circumstance, there is but little inflammatory exudation present, and the vessels contain little blood. When a limited portion of liver is thus affected, the pallid and swollen patch is usually surrounded by an area of congestion; when the whole organ is implicated, the pallor may be universal, or it may be marbled with patches of congestion. As will hereafter be shown, there is reason to believe that the condition known as yellow atrophy of the liver is an inflammation of the kind here referred to.

Inflammation ending in abscess is probably always circumscribed and at the same time necessarily intense. The early stage of suppuration is usually indicated by pallor, opacity, and swelling of a definite patch of

liver substance, the tissues immediately surrounding which and for some distance beyond are generally more or less deeply congested. Soon the affected patch softens and then breaks down. The process is identical with that of the formation of abscesses elsewhere: embryonic cells make their appearance in large numbers, the hepatic cells become swollen, granular, fatty, and fall into detritus, and the web of connective tissue in which they are imbedded liquefies and disappears under the influence of the inflammatory exudation and growth. If the abscess extend, these processes gradually involve the surrounding structures, partly by simple extension, partly by the development of new foci in the immediate vicinity. And, under such circumstances, it not unfrequently happens that abundant shreds and filaments of a pinkish grey hue and soft consistence hang from the parietes of the abscess into its cavity, and that these if traced outwards are found to merge into a pulpy flocculent network, infiltrated with pus, and from the meshes of which the disintegrated liver cells have disappeared. The purulent contents vary in character, and are not unfrequently tinged with bile; they are often glairy and of a greenish hue. Hepatic abscesses vary in their seat, size, and number. They may be found in any part of the liver. They may range from the size of a pin's head up to that of a cocoa-nut, and, indeed, are sometimes much larger than this. In the Netley Museum (according to Dr. Maclean) is an hepatic abscess which contained no less than seventeen pints of pus. They may be solitary, or may amount numerically to 20, 30, or even 100. Idiopathic abscesses are for the most part solitary, or at any rate occur in small numbers. When they are numerous there is reason to suspect a pyæmic origin. It is important, however, not to overlook the remarkable influence which the various tubes permeating the liver exert over the distribution and multiplication of abscesses. Pus or inflammatory lymph gaining entrance into the portal vein may be conveyed in the form of emboli until they become arrested in vessels too small for their further transit; when, as a result, congestion, followed by softening and suppuration of the *aræ* to which the obstructed vessels lead, takes place. Occasionally during the progress of an hepatic abscess a branch of the portal vein in the substance of the liver becomes involved; pus in more or less abundance enters the affected vessel and is thence distributed amongst its ramifications, causing, sometimes the formation of scattered abscesses in some particular district, sometimes a series of branching abscesses due to the conversion of the veins themselves into suppurating channels. Similar consequences, but of more general distribution, may result from suppurative inflammation of the trunk of the portal vein or of some of its tributary branches. Again, some large branch of the hepatic vein may get perforated by an advancing abscess; when, communication with the cava having been cut off by the formation of a plug, the pus may flow backwards into the tributary branches, and a ramifying abscess result. One of the hepatic ducts may be the seat of a like mischance. It may become perforated by an hepatic abscess which may then discharge itself into the bowel; or, the duct becoming obstructed below the seat of perforation,

the pus may be driven back into the smaller branches. Moreover, inflammation, commencing in the biliary ducts, sometimes leads to abundant suppuration, and occasionally to the almost complete destruction of their parietes and the development of irregular branching abscesses. Some of the terminations of hepatic abscesses have been indicated in the foregoing statement. It remains to add that they may discharge themselves in various directions; as, for example, through the external abdominal parietes; through the diaphragm into the pericardium, pleura, or lung; or into the peritoneum, stomach, duodenum, or colon. Sometimes the abscess burrows, and it may then take almost any route: either infiltrating the tissue of the great omentum; or running downwards in the meso-colon or behind the peritoneum and thus finding its way into the cæcum or rectum, bladder or vagina, or taking either of the courses which an ordinary psoas abscess is apt to take. In some instances the abscess ceases to spread, the tissues around get thickened and indurated, and the matter becomes encysted, and undergoes fatty, caseous, or calcareous change.

*Symptoms and progress.*—The symptoms which attend inflammation of the liver are exceedingly various, and often so slight as to elude observation. They include enlargement of the organ, which may be detected by inspection, palpation, and percussion; weight and uneasiness or pain in the hepatic region, which last is often increased, and perhaps only developed, by pressure, change of position, or the respiratory acts; occasional sympathetic pains in the right shoulder, and possibly down the right arm; disturbance of the digestive organs, indicated by fulness, flatulence, nausea, sickness, and loss of appetite; and slight febrile disturbance. Jaundice not unfrequently supervenes, but is rarely intense. The pain is always most severe when the surface of the liver is involved; and is then of a pricking or cutting character, resembling that of ordinary acute peritonitis. It is in this case chiefly that the movements of respiration become affected, as in diaphragmatic pleurisy, that the sympathetic pain in the shoulder manifests itself, and that a dry hacking cough is induced.

The symptoms of hepatic suppuration are in many cases vague and misleading. This is no doubt due in part to the fact that hepatic abscess so often supervenes in the course of dysentery or pyæmia—affections which by the severity of their proper symptoms tend to overshadow those of the hepatic complication. It is not, however, due entirely to this cause; for idiopathic suppuration, independent of dysentery, and the suppuration which complicates hydatid tumours, not unfrequently (for a time at least) fail of recognition. The local indications of abscess are pain and tenderness in the region of the liver, tumour in the same situation, displacement of neighbouring organs, and interference with their functions. Pain and tenderness may be almost entirely absent; and when present they vary largely in intensity and extent. They are generally most severe when the abscess approaches the surface and this becomes implicated. The pain is then, as in peritonitis, of a pricking or cutting character.

When the abscess is deep-seated, it is usually dull and aching. Pain referred to the right shoulder is not unfrequent during the progress of suppuration. Whether or not there be any obvious enlargement of the liver depends partly on the number, partly on the size, partly on the situation, of the abscesses. An abscess, even of large dimensions, situated at the back, or deeply imbedded, may easily escape observation. It may indeed lead to the descent of the anterior edge of the liver, and so induce a belief in the uniform enlargement of the organ, which is of course no sufficient indication of the presence of an abscess. When, however, the abscess is situated more anteriorly, it tends gradually to form a rounded swelling, which increases more or less rapidly in size, protrudes the parietes, and sooner or later probably yields a distinct sense of fluctuation. This protrusion sometimes occupies the scrobiculus, and may then involve also more or less of the umbilical and hypochondriac regions; sometimes it takes place principally upwards, displacing the lungs and heart; not unfrequently it occurs mainly towards the right side of the chest, in which case the base of the lung may be displaced upwards considerably above the level of the nipple, and the corresponding part of the thoracic walls, with the adjoining hypochondrium, may form a smooth round swelling. It is always important in these cases to determine the exact limits of the hepatic mass and of the area of dulness. As regards neighbouring organs, the diaphragm is not only frequently displaced, but from the implication of the convex surface of the liver is often embarrassed in its action, and respiration becomes thoracic, shallow, and painful, and a dry hacking cough and hiccough arise; the stomach, again, is often displaced, and nausea, vomiting, and other dyspeptic symptoms may consequently ensue. The general symptoms due to hepatic abscess are various. The most important probably are those of fever. Fever, however, is sometimes wholly absent, and may indeed be absent during the entire progress of cases attended with extensive suppuration. More commonly, however, there is some elevation of temperature, either at the commencement of suppuration, or at some intermediate period of its progress, or at a late stage when the surface of the liver becomes involved, or during the whole course of the case. The temperature does not commonly rise above  $102^{\circ}$  or  $103^{\circ}$ , presents for the most part morning remissions and evening exacerbations, and is sometimes attended with chills or even severe rigors, which in their severity and periodicity may simulate those of ague. The fever, if persistent, assumes a hectic character, and is attended with profuse perspiration, especially at night time. Jaundice is by no means a necessary accompaniment of hepatic abscess. It is occasionally present, however, and is then usually slight. The condition of the digestive organs varies considerably. Sometimes they are but little affected; sometimes, on the other hand, the tongue may be coated or dry, and thirst, loss of appetite, flatulence, nausea, vomiting, diarrhoea, and other indications of gastro-intestinal irritation or catarrh, may be developed. When the veins or ducts are alone or mainly affected, there may be little or no obvious enlargement of the liver, and scarcely any pain or tenderness. Suppura-

tion in the course of the portal vein and its branches (pylephlebitis) is not very uncommon, as the result probably of inflammation commencing in some of the tributary branches connected with some portion of the bowel. In this affection, the liver is generally decidedly, though not much, enlarged, and there is some pain and tenderness in its situation. For the rest, the symptoms are mainly those of pyæmia, including especially irregular ague-like attacks, attended with rigors, and a temperature running up to  $103^{\circ}$ ,  $104^{\circ}$ ,  $105^{\circ}$  or more, and slight sallowness of skin and conjunctivæ, or even definite jaundice.

Hepatic abscess is always an affection of great danger, and frequently proves fatal. In some cases death is due simply to the impairment of nutrition and the extreme debility which extensive suppuration entails. Sometimes these conditions are associated with the persistence of a febrile temperature, or with the retention of effete matters in the blood; and the patient, previous to death, lapses into a typhoid state, with dry brown or black tongue, subsultus tendinum, and muttering delirium. In a large number of cases, however, complications ensue, dependent mainly on the bursting of the abscess into, or the extension of inflammation to, some neighbouring organ. The nature of these has already been sufficiently considered under the head of morbid anatomy. For their symptoms we must refer to the accounts of the diseases of the several organs which may be thus implicated. In other cases, as has been shown, death is due to pyæmia. When restoration to health occurs, it may be due either to the abscess becoming encysted and undergoing degeneration, or to the discharge of its contents through the abdominal walls, or lung, or into the bowel.

*Treatment.*—The treatment of hepatic inflammation must depend on the nature and severity of the symptoms by which it is attended. Febrifuge or alkaline medicines and saline purgatives or mild laxatives of other kinds are generally indicated. Food of unstimulating character, for the most part farinaceous substances and milk, should be administered. And local pains or uneasiness should be counteracted by hot fomentations or cold applications, or by counter-irritants, such as mustard plasters and the like; or if there be much feverishness, and the local phenomena be at the same time severe, by the use of leeches or the cupping-glasses. Amongst drugs which are frequently had recourse to in the treatment of these affections (especially when they are severe or chronic in character), and which are for the most part highly esteemed, are iodide of potassium, chloride of ammonium, taraxacum, and nitro-hydrochloric acid. During convalescence good diet, change of air, and tonics are always valuable.

In the earlier stages of hepatic suppuration, nothing probably arises to call for special treatment. When, however, the abscess is so far developed as to render its presence pretty certain, the question of evacuating its contents arises. It is a moot point whether it should be allowed to take its own course, to open when and where it pleases, or whether it should be punctured at the earliest possible opportunity. Dr. G. Budd is a strong advocate of the former plan. Many, however, prefer the latter procedure,

and we are of the number. The risks, indeed, which attend the progress of an abscess are, partly from the amount of disorganisation it produces in the liver itself, partly from the uncertainty as to the route it may take, so serious, that they can scarcely be aggravated by operative procedure, and they may be largely diminished by it. We believe the best plan is to evacuate the contents, as soon as opportunity offers, by means of a fine trocar and cannula, with or without the aid of the aspirator. This operation may generally be safely effected even if no adhesions have formed between the liver and the abdominal walls. It is well to avoid the admission of air, and to employ an evenly and firmly applied bandage afterwards. The operation may be repeated from time to time. If the discharge become offensive, and adhesions have formed, a free opening should be made and maintained; and the cavity of the abscess should be occasionally washed out with weak solutions of some antiseptic, such as chlorinated soda, nitric acid, carbolic acid, or quinine. During the progress of these cases the patient's strength should be supported by tonics, stimulants, and nutritious diet. Opiates are always of great value. It may of course be necessary to treat gastric and other complicating disorders.

#### IV. CIRRHOSIS OF THE LIVER

##### A. *Atrophic Cirrhosis* (*Hobnailed or Drunkard's Liver*)

*Causation.*—Atrophic cirrhosis is almost always a consequence of the persistent excessive use of alcoholic beverages. This, however, is not the sole cause of the disease. For it is occasionally met with in persons who have been undoubtedly temperate in their habits, and in children who have never taken stimulants. It is probably more common in men than in women; and is generally first recognised in persons above 35.

*Morbid anatomy.*—In typical cases the liver is much reduced in size, rounded, studded with hemispherical elevations from about  $\frac{1}{4}$  to  $\frac{1}{3}$  inch in diameter, and obtusely margined. Moreover, generally its capsule is thickened, and old adhesions bind it to the diaphragm and neighbouring organs. On section it is found to be remarkably indurated; and the same nodulated condition which marks the surface is manifest throughout its substance. This nodulation is due to the permeation of the liver by a network of dense greyish fibroid tissue, within the meshes of which the proper parenchyma of the organ is contained in the form of roundish bodies, varying roughly from the size of a tare to that of a large pea. The fibroid growth occupies mainly the capsule of Glisson surrounding the small branches of the portal vein, and the vaginal veins, which give rise to the interlobular plexuses, and extends thence in a greater or less degree into the interlobular spaces. On close inspection it will generally be seen: that the larger hepatic nodules are made up of smaller ones—the latter comprising several hepatic lobules; and, moreover, that

there is always a more or less definite line of demarcation between the annular bands of fibroid tissue and the groups of hepatic lobules which they circumscribe. The proper hepatic tissue of the hobnailed liver may present its normal hue; but not unfrequently it is fatty and jaundiced, and has a light or orange-yellow tint—whence the name ‘cirrhosis.’ There is reason to believe that in the early stage of the disease the liver is somewhat enlarged, and at the same time smooth on the surface. Atrophic cirrhosis appears to originate in a chronic inflammatory condition of the branches of the portal vein above indicated, attended with the abundant appearance in the tissues immediately surrounding them of embryonic cells, which undergo slow conversion into cicatricial fibroid tissue, and then gradually contract. The inflammatory process rarely implicates the substance of the hepatic lobules even at their periphery; but by the compression to which they are subjected the liver-cells become flattened and atrophied, and after a while disappear to a greater or less extent. It is an interesting fact, in connection with the morbid anatomy of the disease, that the adventitious fibroid growth (notwithstanding that by involving the smaller branches of the portal vein it interposes a serious obstacle to the portal circulation) is itself, unlike ordinary cicatricial tissue, richly permeated with large tortuous vessels of capillary character. These, though still communicating in some degree with the portal system, seem specially to serve as a route for the passage of the blood of the hepatic artery to the intralobular vessels; and it is probably in consequence of their presence or development that the nutrition of the liver and the formation of bile are usually maintained to the last. Further, as the smaller biliary ducts are not necessarily implicated, bile is not as a rule retained, and jaundice rarely occurs. The obstruction of the portal veins leads to hyperæmia and distension of the tributary vessels, and consequently to dropsy, hemorrhage, enlargement of the spleen, development of hæmorrhoids, and vicarious dilatation of veins—more especially of those about the umbilicus and the abdominal walls above the umbilicus.

*Symptoms and progress.*—Atrophic cirrhosis is for the most part very insidious in its progress. In many cases no symptoms manifest themselves, sufficient at any rate to attract attention, until the affection is far advanced; in many, the patient suffers only from the usual symptoms of dyspepsia or chronic gastric catarrh—symptoms which may equally occur in the absence of hepatic disease; in many, he has vague indications of ill-health with progressive loss of strength and emaciation, and these phenomena may be associated with distinct evidence of similar disease going on in the kidneys; in some, no doubt, slight signs of hepatic derangement show themselves from time to time, and, in association with the habits or history of the patient, reveal to the careful observer the momentous changes which are going on within. The hobnailed liver, excepting perhaps in its earlier stages, is usually atrophic, and the normal hepatic dulness is consequently diminished in area or suppressed; but the presence of an enlarged liver by no means forbids the diagnosis of this disease. Its chief indications are the supervention of abdominal dropsy, and the occurrence of hemorrhage

(often profuse) from the stomach and bowels. The more frequent of these is no doubt ascites, but it does not necessarily become developed even in fatal cases; and even, when once it has appeared, will sometimes subside under appropriate treatment, and never recur. Hæmatemesis and melæna are sometimes the first indication of the presence of the hepatic disease; and the first attack may prove fatal. When once such hemorrhage has occurred, it has a marked tendency to recur; and it is a phenomenon of very fatal augury. Jaundice supervenes in a minority of cases, and is very rarely intense. Besides the symptoms just enumerated, others of more or less importance are commonly present. There is usually progressive and finally extreme emaciation, with a sallow or earthy cachectic aspect. There is generally more or less obvious disturbance of the digestive functions; the tongue becomes coated or dryish, and there may be thirst, loss of appetite, sense of flatulent distension, nausea and vomiting; the bowels may be constipated or relaxed, and, indeed, diarrhœa, which is apt to assume a dysenteric character, is not an unfrequent precursor of death; the motions generally are pale; piles are of common occurrence; the urine is often scanty and loaded with lithates; and there is a liability for hemorrhage to take place from the various mucous membranes and beneath the skin. The tendency of cirrhosis is always to a fatal issue, but the duration of the disease is almost impossible to ascertain. It may certainly last for many years; but when once distinctive symptoms have shown themselves, the patient's days are numbered. He may, however, even then survive for several years. The immediate causes of death are various. The natural termination is by gradual asthenia. But the patient is often carried off by the consequences of the ascitic accumulation, by gastro-intestinal hemorrhage, by profuse alvine discharges, by peritonitis, or by the supervention of pneumonia or other pulmonary complications. Not unfrequently also the hepatic affection is only one of a series of lesions of an allied character involving, it may be, heart, lungs, spleen, kidneys, and other organs.

### B. *Hypertrophic Cirrhosis*

*Causation and morbid anatomy.*—This is a form of cirrhosis which has long been recognised and, so far as its coarser features are concerned, described by pathologists. But it has only comparatively recently been distinguished from the ordinary hobnailed liver as a condition having a different pathology and different consequences. The causes of hypertrophic cirrhosis have not been clearly established; but at any rate there is less distinct evidence that it is connected with alcoholic intemperance than in the case of atrophic cirrhosis. In this condition the liver is enlarged, sometimes to twice or even thrice its normal size; is tolerably smooth on the surface; and retains its normal form and its sharp well-defined anterior edge. It is extremely dense in texture, and on section is found to be largely infiltrated with dense greyish slightly translucent

<sup>1</sup> Hanot, *Étude sur une Forme de Cirrhose hypertrophique du Foie*. Thèse de Paris, 1876. Chareot, *Leçons sur les Maladies du Foie, &c.* Paris, 1877.

connective tissue. This does not form a distinct net-work as in the hob-nailed liver, circumscribing definite groups of hepatic lobules, but is rather a diffused growth in which the remnants of the hepatic parenchyma are scattered irregularly in yellowish masses from the size of a poppy-seed to that of a pea. In some parts the hepatic tissue predominates and there is an approach to the hobnailed condition; in some almost every remnant of the natural structure has disappeared, and dense fibroid tissue alone remains. The remnants of hepatic parenchyma vary in colour from orange-yellow to green. Microscopically the fibroid growth shows the same characters as those of ordinary cirrhosis; and in its early stage and when it is in progress of extension it consists mainly of embryonic cells. But it commences, not so much from the terminal branches of the portal vein, as from the interlobular branches of the bile-ducts, and from those branches of them which occupy the periphery of the lobules. The morbid process begins in fact with the development of embryonic tissue immediately around these channels; whence it spreads, implicating the portal vessels at a later period. It tends also to involve the lobules themselves, which as a rule escape in atrophic cirrhosis. The affected ducts become largely dilated and their epithelium increases in quantity. The smaller branches, indeed, get blocked up with their accumulated contents. The liver cells are atrophied, contain biliary pigment, and are more or less fatty. In this disease the obstruction which the fibroid growth causes is chiefly of the ducts, and the portal circulation is not necessarily implicated.

*Symptoms and progress.*—Hypertrophic cirrhosis is a disease mainly of adult life, and like the atrophic variety is of slow progress. The ordinary symptoms of derangement of the gastro-intestinal organs, gradual emaciation, and failing strength belong to both affections. But whereas the main consequences of hob-nailed liver are ascites and gastro-intestinal hemorrhage dependent on obstruction to the portal system; in this case these phenomena are for the most part conspicuous by their absence, and dropsy, if it occurs at all, comes on late, and then probably only in a slight degree. On the other hand, jaundice, which is generally absent, and never well developed in atrophic cirrhosis, is apt to appear early in this disease, to acquire considerable intensity, and to persist. It is liable, however, to fluctuations. Moreover, with the jaundice we have all the characteristic phenomena which attend and follow on the presence of bile in the blood; and consequently such patients are specially liable to cerebral and other toxæmic symptoms. The detection by palpation of an hypertrophied, hard, and sharp-edged liver is an important element in the diagnosis of these cases. The spleen is usually hypertrophied. But the superficial abdominal veins are probably not enlarged.

### C. Other Conditions allied to Cirrhosis

*Causation and morbid anatomy.*—Among these we may enumerate: the diffused form of cirrhosis observed mainly in syphilitic children; chronic inflammatory conditions involving especially the capsule of Glisson

surrounding the larger vessels and ducts; and chronic perihepatitis attended with compression and atrophy of the liver.

1. The cirrhotic condition of liver, which occasionally arises in the course of syphilis, whether in the adult or in infants, and which is not unfrequently associated with the formation of gummata, is characterised (see Cornil and Ranvier), as is hypertrophic cirrhosis, by uniform enlargement of the organ; but the enlargement is due to the general development of embryonic tissue, not simply in the interlobular spaces, but in the lobules themselves, between the columnar groups of cells, and even separating the individual cells from one another. In this affection the liver is at first readily lacerable, but as the embryonic tissue becomes converted into fibrous tissue the organ becomes indurated; and its general condition acquires a close resemblance to that of hypertrophic cirrhosis. 2. It not unfrequently happens, sometimes in the course of syphilis, sometimes in connection with obstructive affections of the ducts, but often under conditions which are not understood, that growth of fibroid tissue takes place along the vessels and ducts which enter at the transverse fissure. This condition is sometimes general, sometimes limited to certain regions; and may have the effect of causing more or less obstruction of the ducts or portal veins or both; and frequently leads to the formation of deep fissures on the surface of the liver, and to a lobulated condition of that organ. 3. Perihepatitis may occur as a part of general peritonitis; and generally takes place in a greater or less degree in connection with the different varieties of cirrhosis. Sometimes the fibroid investment is exceedingly thick and dense; and by its contraction compresses the liver into a roundish mass with obtuse, ill-defined edges. This sometimes occurs when the general texture of the liver is healthy, but necessarily causes compression, atrophy, and obstruction of vessels and ducts.

*Symptoms and progress.*—It would be difficult to define the symptoms and consequences of these several conditions. It is sufficient to say that besides inducing, like hobnailed liver, general symptoms of ill-health, they are likely in various degrees to be attended sooner or later with the specific consequences of obstructive hepatic disease—namely, ascites, gastrointestinal hemorrhage, and jaundice.

#### D. Treatment of Cirrhosis

As regards hobnailed liver, more important than its treatment by medicine is the avoidance of those habits of indulgence in alcoholic drinks on which it seems mainly to depend; and it should be borne in mind that it is not so much the occasional getting drunk which is dangerous in this respect, as the habit of constant tipping. Even if the disease be in progress, the discontinuance of this habit must be of real benefit to the patient, inasmuch as the condition which keeps the morbid process active then ceases. It is important that this fact should not be forgotten; for the victim of atrophic cirrhosis for the most part so craves for his accustomed stimulant that the physician is apt unwisely to indulge him in his cravings.

But besides abstinence from alcohol the patient should attend carefully to hygienic measures: his diet should be light, nutritious, and not too stimulating or too abundant; he should keep good hours, be warmly clad, and take moderate exercise. Further, he should be put under a course of vegetable bitters, with (especially if there be gastro-intestinal catarrh) the addition of some stomachic. Or he may take one of the drugs often recommended for cases in which hepatic inflammation is assuming a chronic character—namely, iodide of potassium, chloride of ammonium, taraxacum, or nitro-muriatic acid. The bowels should be kept freely open, but violent purging should be avoided. When the various late complications or results, such as ascites, hæmatemesis and melæna, dysentery, or jaundice, supervene, they will of course require special treatment. But for details we must refer to the articles devoted to these several subjects.

The remarks just made in regard to the treatment of atrophic cirrhosis are applicable in the main to the other forms of chronic hepatitis. If, however, there be reason to suspect a syphilitic origin, it is obvious that antisyphilitic remedies should be prescribed.

---

## V. CONGESTION OF THE LIVER (*Nutmeg Liver*)

*Causation.*—Congestion of the liver necessarily attends inflammation of the organ; it occurs also in connection with over-eating, excessive use of alcohol, sedentary habits, and exposure to atmospheric influences, especially great heat; and it is a common consequence of ague or exposure to malaria, and of various febrile and inflammatory disorders. The most interesting form, however, of congestion is probably the mechanical congestion which arises in the course of obstructive lung and heart diseases, more especially diseases of the mitral valve and valves of the right side of the heart. It is this form of congestion alone which we shall now consider.

*Morbid anatomy.*—Congestion of the liver is attended with enlargement of the organ due to distension of its vessels, mainly its veins and capillaries, with blood. When this is general the liver structure presents a uniform deep-red hue, and blood escapes in abundance from the cut surface. In cardiac or mechanical congestion it is the hepatic veins and their minute branches occupying the centres of the lobules which are chiefly if not exclusively involved. These become dilated and full of blood, and the liver consequently often undergoes considerable increase in bulk. If sections of the organ be made at this time it will probably be found that the centres of the lobules are deeply congested while their peripheral parts are pale. With the progress of the disease the hepatic texture undergoes important changes: in consequence of the increasing dilatation of the intralobular hepatic veins the cells which lie in their meshes undergo atrophy and perhaps finally disappear; the cells immediately bounding this region often become deeply jaundiced and the seat of granular biliary

pigment, and hæmatoidine crystals are occasionally deposited; and the peripheral cells of the lobules get distended with oil. In this stage the liver is often larger than natural, though probably smaller than it was at first; it is apt to be somewhat granular on the surface, with a more or less thickened capsule; it presents some degree of induration; and on section the surface is found to be thickly studded with small circles or festoons of an opaque buff or bright yellow colour, interwoven with discs or small lobulated patches of intense, perhaps black, congestion. The appearance has been not unaptly compared to that of the sectional surface of a nutmeg. In connection with atrophy of the cells of the central parts of the lobules, a development of fibroid tissue tends to take place, and thus a condition allied to cirrhosis may ultimately be developed.

*Symptoms and progress.*—The symptoms of congestion of the liver or of the congestive hepatitis which takes place in the course of obstructive cardiac or pulmonary disease are: uniform enlargement of the organ, which probably descends an inch or two below the lower margin of the right ribs, and encroaches also to an abnormal extent on the right half of the thoracic cavity; pain and fulness in the hepatic region, with considerable tenderness on pressure or percussion; pain or tenderness on lying on the right side; pain also on lying on the left side from the tendency of the liver to drag; and pain on drawing a deep breath or coughing. Slight jaundice is apt to supervene and to persist after all other symptoms of hepatic affection, excepting enlargement of the organ, have subsided. It is in these cases that hepatic pulsation is occasionally observed. Hepatic engorgement comes on, as a rule, late in the progress of cardiac and pulmonary diseases, and although it often subsides under treatment, it is very apt to recur, and then to become permanent. When the congestion has become chronic and the liver shrunken and indurated, ascites and other consequences of portal obstruction, as in ordinary cirrhosis, are apt to ensue.

The *treatment* of hepatic congestion is mainly of course that of the pulmonary or heart disease which causes it. In other respects it may be regarded as identical with what has already been prescribed for inflammation of the ducts of the liver or the earlier stages of acute hepatitis.

---

## VI. MORBID GROWTHS

### A. *Tubercle*

This affection is much more common in the liver, in connection with tuberculosis of other organs, than is generally supposed, but has no clinical importance. Miliary tubercles are most frequently met with and are often present in considerable numbers; but owing to their close approximation in colour to the hepatic lobules, and their extreme minuteness, are apt, excepting they be at the surface, to elude detection. Occasionally tubercles of the average size of a pea or bean are observed

These always present a central cavity full of broken-down tissue and biliary colouring matter, with a capsule of yellowish or greyish tubercular growth.

### B. *Syphilis*

*Morbid anatomy.*—Syphilitic disease is recognised post mortem chiefly by the presence of gummata, which have already undergone retrogressive changes. These are opaque, buff-coloured, dense, tough masses, rounded or irregular in form, and varying from about the size of a pin's head to that of a chestnut. They are rarely solitary, and are often grouped in clusters of considerable bulk. They are incapable of enucleation, and are embedded in dense fibroid or cicatricial tissue, which is continuous, on the one hand, with the bodies just described, on the other hand, with the surrounding hepatic texture. They are mostly solid; but occasionally, when one is permeated by a duct, the latter is broken down into a cavity within it. Wherever these masses with the surrounding cicatricial tissue are present, the hepatic surface which corresponds to them is thickened, drawn in, and sometimes very deeply indented—facts which prove the chronic nature of the affection, and that much contraction of tissue has attended its progress. Not unfrequently, in cases where many of these tumours are present, we also find dense masses of cicatrix-like tissue, which are either free from obvious tumours in their interior, or which in place of them present merely a few opaque or gritty particles.

The conditions above described are, however, only the last phases of a more acute syphilitic affection. The influence of the syphilitic virus on the liver is in the first instance to cause interstitial inflammation, which, as we have shown, has considerable resemblance to that of the early stage of ordinary cirrhosis. This affection may be general throughout the liver, or confined to certain areas; and it is in connection with it that, sooner or later, gummata make their appearance. These are due to the active proliferation of certain of the cell-elements of the newly formed fibroid tissue, which increase in number and diminish in size, and collectively form tumours having a close resemblance to granulation-tissue or tubercle in the early stage. These growths then rapidly degenerate in their central parts, while they increase peripherally, so that at an early period they present caseous masses surrounded by a thin rim of living cell-growth. After a while they cease to enlarge, and the whole mass undergoes caseous degeneration. Gummata may occur in any region; they are common on the convex surface of the liver, and especially, as Virchow points out, in points exposed to injury. They are common, also, in the neighbourhood of the transverse fissure, and may there seriously interfere with the permeability of the ducts and vessels. They usually vary individually in size between that of a pea and that of a walnut; but they may be larger or smaller, and are often aggregated. Such aggregations may attain the size of the fist. Although interstitial hepatitis is a common result of congenital or hereditary syphilis, the firm cheesy masses just described are rarely discovered in that variety of the disease.

*Symptoms.*—The symptoms which may be looked for in hepatic syphilis are those of cirrhosis in its various stages, especially, therefore, ascites, intestinal hemorrhage, and jaundice. But it must be admitted that syphilitic disease is, from first to last, often unattended with symptoms, and that it is not unfrequently discovered post mortem in cases where its presence during life had never been suspected. In the earlier periods of the disease a persistent hectic temperature is sometimes almost the only evidence of its presence. When, however, the gummatous growths obstruct the vena portæ or the hepatic ducts, the symptoms due to such lesions will necessarily manifest themselves with considerable, and perhaps sudden, intensity. The detection of irregularity of form, or hard rounded or nodulated but sluggish tumours, in the liver is an important aid to diagnosis. The chief grounds, however, for suspecting the presence of syphilitic disease in this organ would be the association of symptoms of hepatic disorder and presence of tumour with a history of syphilis and visible indications of its presence in a constitutional form.

*Treatment.*—In addition to the treatment suitable for cirrhosis and its consequences, the use of antisymphilitic remedies is obviously indicated in the treatment of hepatic syphilis.

### C. Non-malignant Growths

Under this head we may make a brief reference to two varieties of morbid formations which have little more than a pathological interest. These are *simple cysts* and *cavernous tumours*. The latter are small, blackish, spongy masses, rarely exceeding the size of a filbert; replacing definite portions of hepatic substance; and consisting of irregular intercommunicating vascular spaces, separated from one another by trabeculæ of fibrous tissue covered with pavement epithelium. Simple cysts vary from scarcely visible points up to the size of an orange. They are sometimes solitary, and are then usually situated about the middle of the anterior edge of the liver. Occasionally they are present in enormous numbers, when they display all grades of size and varieties of grouping. They are generally thin-walled, and in some cases give evidence of their enlargement by the coalescence of neighbouring cysts; they are lined with pavement epithelium, and usually filled with clear serous fluid. The smaller cysts sometimes contain yellowish or brownish colloidal masses like those found in renal cysts. Cysts, however numerous they may be, rarely, if ever, induce hepatic symptoms; it is possible, of course, that the presence of one of large size in relation with the anterior edge might be detected by manual examination; as a matter of fact, however, they are rarely, if ever, recognised during life. The most interesting point in connection with them is the fact of their comparatively frequent association with cystic developments in other organs, more especially in the kidneys and spleen. They must not be confounded with hydatid cysts.

*D. Malignant Growths*

*Morbid anatomy.*—Malignant tumours of the liver are usually secondary to similar growths originating elsewhere in the body, and especially, perhaps, to such as are developed in the other chylipoietic viscera. Not unfrequently, however, they are primary. No age is exempt from liability to the disease; yet it rarely occurs before adult age, and is most common in persons of middle and advanced life. It has been met with in young children, and in them is probably always a secondary manifestation. The influence of sex is unappreciable.

Malignant disease appears in the liver in two forms: either as isolated tumours or as a more or less general infiltration. In the former case the tumours vary in size from that of a good-sized orange, or even a coconut, down to minute granules, which the naked eye may fail to recognise. Their general form is globular, unless the coalescence of neighbouring masses, or accidental circumstances, have led to their irregular development. When they involve the surface of the liver, those areas of disease which are immediately subjacent to the capsule, and which are generally circular, assume a peculiar cupped appearance, due to the presence of a prominent tumid peripheral ring, circumscribing a central concave depression. This cupping is very characteristic, and may frequently be recognised in tumours not more than a line or two in diameter as readily as in such as have attained the bulk of a chestnut or orange. There is usually well-marked vascularity of the superficial aspect of these tumours, and especially of their peripheral portions and of the liver-structure immediately surrounding them. The tumours grow at their margins, partly by progressively invading the healthy tissues bounding them, partly by the formation in their immediate neighbourhood of new foci of disease, with which they gradually coalesce. But while the marginal growth is in progress the central portions fall into degeneration. This may be fatty, caseous, or even calcareous, or connected with hemorrhagic extravasation. Occasionally the central portions undergo liquefaction, and become converted into cysts containing a milky or watery fluid. These several forms of degeneration do not, as a rule, occur indiscriminately; each one, in fact, indicates to some extent an inherent peculiarity in the tumour in which it occurs, and which is shared more or less by all the other tumours which are in genetic relation with it. It is to the combination of active peripheral growth with central retrogression and necrosis that the superficial cupping to which reference has been made is mainly referrible. Malignant tumours may occur in any part of the hepatic substance; and may vary numerically from one or two to an innumerable multitude. In the former case they are usually primary, and it is here that probably their greatest size is attained. In the latter they are generally secondary to growths elsewhere.

The diffused or infiltrating form of malignant disease is much rarer than the other. In this case we find the liver generally, or large portions of it, greatly enlarged, but retaining their normal shape; the enlargement

being due to the abundant dissemination of small growths, more or less indistinctly defined from the liver-tissue, and tending to run together, so as to give to both the outer and the sectional surface of the affected organ a spotty, reticulate, or uniformly morbid character. Sometimes, indeed, the naked eye fails to detect in the enlarged liver any traces of normal hepatic tissue. The presence of distinct rounded tumours may be associated with the condition here described.

Of the several forms of malignant disease which attack the liver, the carcinomata are the most common. The variety of cancer most frequently met with is the encephaloid, of which several sub-varieties, not, however, calling for description, exist; scirrhus is more rare; and still rarer than scirrhus are melanotic cancer and colloid cancer. Most of these appear under the form of isolated scattered masses. Sarcomatous malignant growths are comparatively unfrequent. The most common and interesting of them is the melanotic variety, which is usually secondary to similar disease of the choroid coat of the eye, or of pigmentary nævi. Melanosis is usually very widely distributed throughout the organ; the tumours are small and tend to coalesce; and the condition above described as 'infiltrating' is apt to be produced; the liver often becomes enormously enlarged, and assumes, from the intermingling of melanotic spots with spots of colourless growth and remnants of hepatic texture, an appearance which has been aptly likened to that of granite. Melanotic masses of considerable bulk, however, are not uncommon. Other forms of sarcoma (spindle-celled sarcoma, for example, and the closely related myxoma) have been discovered in the liver, secondary to similar growths in remote organs. True epithelioma of the liver is scarcely more than a pathological curiosity. Cylindrical-celled epithelioma, however, or adenoma, secondary, for the most part, to gastro-intestinal disease of the same kind, is of much more frequent occurrence. Its tumours are scarcely distinguishable, excepting microscopically, from those of ordinary carcinoma. Lastly, lympho-sarcoma, or lymphadenoma, is often developed in the liver. This may form independent tumours, like carcinoma, but seems specially to affect the capsule of Glisson and the interlobular tracts; so that, in some cases, it involves the liver by ramifying through it with the portal vessels, in some it follows the ordinary distribution of the fibrous growth of atrophic cirrhosis, but in either case is apt to develop here and there into manifest tumours. Other forms of malignant disease besides lymphadenoma are liable to invade the liver from the transverse fissure. In cases of gastric or peritoneal cancer especially, the small omentum is very commonly infiltrated with cancerous growth, which thence propagates itself along Glisson's capsule, surrounding and compressing, or otherwise involving, the veins and ducts. Again, the lymphatic glands in this situation are often affected secondarily to hepatic or other neighbouring malignant disease, and may by their enlargement implicate the same channels.

*Symptoms and progress.*—The symptoms which attend malignant disease of the liver are in the main identical with those of cirrhosis and

other structural diseases of the same organ. They comprise : alterations in the form and size of the organ, with local pain or uneasiness ; impediment, mechanical or other, to the due performance of the hepatic functions ; mechanical interference with the functions of neighbouring organs ; and general impairment of nutrition. Increase of size and alteration of shape furnish important indications of the presence of hepatic malignant tumours. The increase may be either uniform, or, as is more commonly the case, dependent on the formation of rounded projecting lumps, which may often be readily distinguished by the hand. Mere increase of size, however, is not so indicative of the morbid conditions in question as is rapid progressive increase ; nor is the simple fact of the presence of irregularity from outgrowths so suggestive as the progressive enlargement and development of such excrescences, and the existence of a certain degree of hardness and resistance which is not usually observed in mere cystic formations. It must be borne in mind, however, that malignant disease is often present in a liver which is not noticeably altered in form or size : the growths may be few and small, or they may occupy the posterior part of the organ, or the liver itself may be concealed by the overlapping of distended and adherent bowel, or by other conditions. And, further, tumours of the stomach, or of the retro-peritoneal glands, or even of the abdominal walls, may seem from their position to be of hepatic origin. Pain is, no doubt, a frequent attendant on hepatic malignant disease. Sometimes it is excruciating, and apt to come on in paroxysms ; but it is often absent, and may be totally absent from first to last. Jaundice, usually due to obstruction of some of the hepatic ducts, makes its appearance sooner or later in a considerable number of cases. It is rarely intense, unless the main duct be involved ; and hence it is chiefly in those cases in which the disease attacks the lesser omentum, and extends thence into the transverse fissure, that deep jaundice becomes developed. Jaundice, however, is by no means a necessary result, and is not unfrequently absent from the most extreme cases—cases in which the whole hepatic texture seems to be replaced by the morbid growth. Ascites is perhaps even more rarely than jaundice a direct consequence of malignant disease of the liver. It is often, no doubt, developed during the progress of the case, and may be due, as in cirrhosis, to impediment to the flow of blood through the portal vessels ; but it is usually comparatively small in amount, and dependent either on peritoneal inflammation or on other abdominal complications. When, however, the portal vein is distinctly obstructed, the ascites may be considerable, and other consequences of portal obstruction, such as melæna, may ensue. In most cases ascites is absent. As regards neighbouring organs, the pressure of the enlarged and possibly painful liver is apt to induce functional disturbance of the stomach on the one hand, and pain and difficulty of breathing, and perhaps cough, on the other. General impairment of nutrition, debility, and emaciation are usually marked phenomena of the progress of the disease. Scanty secretion of urine, with

abundant deposit of vermilion or carmine coloured urates, is commonly observed.

In most cases malignant disease of the liver is associated with similar disease of other organs ; and the symptoms which the patient presents are, therefore, of complicated origin. This fact, while it may be of the greatest value in enabling us to form a correct diagnosis of the malady under which he is labouring, often renders it difficult to determine how much and which of his sufferings are due to the hepatic lesion. As of malignant disease generally, so no doubt of that affecting only the liver, it may be regarded as generally true : that the symptoms are insidious and progressive ; that the disease has usually made considerable progress before the suspicion arises that the patient is ill ; that this suspicion is first aroused, either by the gradual creeping on of emaciation, debility, and cachexia, or by the slow supervention of gastric symptoms, or by a sense of fulness, heat, or pain—continuous or paroxysmal—in the hepatic region, or lastly by the discovery of obvious tumours. During the further progress of the case all the symptoms of this period of invasion are apt to become commingled, and the special phenomena which we have attributed to the declared disease to supervene. It must not, however, be forgotten that malignant disease of the liver may prove fatal without having ever been attended with some of those symptoms which would seem to be most typical of it : not only, as we have pointed out, may there never be obvious tumour, hepatic pain, jaundice, ascites, or distinct impairment of the digestive functions, but the so-called ‘cancerous cachexia’ may never be distinguishable, and the patient, instead of emaciating, may remain in good flesh, or even become fat.

From the difficulty of determining the date at which it commences, it is impossible to determine, even approximately, the duration of hepatic malignant disease. Nor is it important to do so. It is sufficient for practical purposes to know : that when once the disease has given clear evidence of its presence, the patient rarely survives beyond twelve months ; and that generally his death occurs within six or eight months. The natural cause of death is gradually increasing asthenia ; but the fatal event is apt to be accelerated by the occurrence of peritonitis or other complications.

*Treatment.*—Medical skill is powerless to arrest the progress of the morbid growths under consideration. All that the physician can do is, to relieve pain and uneasiness by opium or other sedatives, or by local measures ; to check vomiting ; to obviate constipation ; and generally to aim at relieving the various symptoms which distress the patient ; and by hygienic and other measures to maintain, as far as possible, his general health and strength.

---

## VII. HYDATIDS OF THE LIVER

*Morbid anatomy.*—These parasites affect the liver more frequently than any other organ; they are not uncommonly developed, however, in various parts of the sub-peritoneal connective tissue, more especially that of the pelvis. In the liver hydatid tumours are usually solitary; but sometimes two or more are developed there simultaneously; and occasionally also such tumours in the liver are associated with other similar tumours elsewhere in the abdominal cavity. Their size varies: they are not unfrequently met with as large as a child's head, and containing several pints of fluid; but they are slow in attaining these dimensions; and, although the exact period during which they live and grow is uncertain, there is no doubt that it occasionally extends to at least ten or fifteen years, possibly even to twenty or thirty. They are for the most part globular in form, unless bands or ligatures, or other accidental conditions, have interfered with their development. In the liver they most frequently involve the right lobe, a fact probably due simply to its comparatively large size. Hydatids appear to originate in the hepatic substance, which becomes displaced by them in the course of their development, and at the same time the seat of fibroid growth and induration in the layer which immediately surrounds them. By this means a kind of fibrous capsule is formed. In most cases there is no communication between the hydatid tumour and the hepatic ducts; sometimes, however, a large, and even a primary, duct may be found leading directly into the cavity, and its open continuation and that of some of its branches, studded with the orifices of their numerous tributaries, may then be seen ramifying upon its walls. The normal event of hydatid tumours, and one which is fortunately far from uncommon, is the death of the parasite, and the degeneration and contraction of the tumour. This has already been sufficiently described; it may, however, be added that hæmatoidine crystals, derived from the biliary colouring matter, are frequently met with in such degenerated cysts. Other events of not uncommon occurrence are the rupture of the cyst by accidental violence and its suppuration.

*Symptoms and progress.*—Hydatid tumours are rarely attended with pain, or even uneasiness, excepting by reason of their bulk and the pressure they exert on neighbouring parts, or in consequence of the supervention of inflammation. Generally, indeed, the patient's attention, or that of his friends, is first attracted by the discovery of gradual and at the same time more or less unsymmetrical abdominal swelling. So that, when the case first comes under medical observation there is generally an obvious tumour in some part of the abdomen, and the question is consequently not so much whether or not a tumour is present, as what the nature of the existing tumour is.

Uninflamed hydatid tumours, which abut upon the surface, usually appear as rounded, tense, elastic swellings, free from pain or tenderness. They often fluctuate distinctly, and are not unfrequently attended with the peculiar hydatid thrill, first described by Briançon and Piorry. This, which

is best recognised by placing the left hand flat upon the tumour, and then percussing sharply with the fingers of the right hand, consists in a peculiarly long-sustained tremor, reminding one of that experienced on an iron railway bridge during the passage of a train over it. It is due to the same cause as the ordinary ascitic thrill, but its distinctive character depends on the extraordinary elasticity of the hydatid membrane, and the consequent fineness and long persistence of vibrations excited in it. It is an interesting and important fact that this peculiar thrill may often be elicited with marvellous distinctness in peritoneal hydatid tumours no larger than a pigeon's egg, which are so tense and hard and thick-walled that they feel like solid masses, and but for this thrill might be taken for malignant or other neoplasms. The nature of the swelling, however, may generally be placed beyond the possibility of doubt by tapping. The fluid which comes away from the living hydatid cyst is transparent and colourless like water, limpid, containing an excessive quantity of chloride of sodium, and as a rule neither albumen nor fibrinogen. Its specific gravity varies from about 1008 to 1013.; and its reaction is neutral or slightly alkaline. Further, it may contain echinococci or microscopic hydatids.

The position of the tumour will necessarily vary with its seat of development. If in the liver, it perhaps most commonly projects forwards — occupying the scrobiculus, or this with more or less of the adjoining abdominal regions; but it may also protrude directly upwards, pushing the heart before it upwards and to the left; or it may displace the right half of the diaphragm, together with the base of the lung, at the same time distending the lowermost zone of the right side of the chest; or again it may be developed in the posterior region of the liver, and so elude detection. It is impossible to lay down any rules with regard to the situation of hydatids when they originate in other parts of the abdominal cavity. Suffice it to say: that they are often multiple and movable; that they may, according to circumstances, assume the position of renal, omental, ovarian, uterine, aneurysmal, or other growths; and that it is with these mainly, especially if they be cystic, and with hepatic swellings, more especially abscesses and dilated gall-bladders, that hydatid tumours may be confounded. When displacing the right lung upwards, and distending the corresponding part of the chest, they may simulate pleuritic effusion. Further, an hydatid cyst may be separated from the surface by a considerable thickness of the tissue in which it originates, or by an exceedingly thick and dense capsule, and hence may be mistaken for a solid tumour; or, owing to the simultaneous development of several cysts, or to various other accidental circumstances, it may appear nodulated or multiple, and may present different degrees of consistence and elasticity at different points, and so may easily be taken for a lobulated malignant growth, or for a compound ovarian or other cystic tumour. The diagnosis of a contracted and degenerated cyst, even if occupying a situation readily accessible to examination, would, without the guidance of a clear history, be exceedingly difficult, if not impossible.

Hydatid tumours are not always unattended with symptoms: they may, from their bulk or situation, interfere seriously with respiration; they may cause vomiting and other dyspeptic phenomena; they may compress the hepatic ducts and so induce jaundice, or the portal vein, causing ascites, or the inferior cava, leading to anasarca of the lower extremities and probably congestion of the kidneys; and hence by the gradual supervention of asphyxia, asthenia, or other conditions, death may after a while ensue. The sudden rupture of hydatid tumours, with the escape of their contents into the peritoneal cavity, is usually followed by rapidly fatal peritonitis. The symptoms due to suppuration are sometimes obscure, sometimes very well marked; they are those, however, which usually attend extensive suppurative inflammation. The hydatid cyst in fact becomes converted into an abscess, and comports itself in its further progress exactly as any other large hepatic abscess. It increases more or less rapidly in size, and after a while discharges its contents either at the external abdominal surface, into the pleura, through the lung into the pericardium, into the stomach, intestine, or abdominal cavity, or into the hepatic ducts and thence into the duodenum. Other rare terminations have been met with, such as by perforation of the vena cava, or right auricle of the heart. The proof that an hepatic or abdominal abscess is of hydatid origin rests on the discovery of hydatid membranes, echinococci or their debris in the pus which escapes. The hooklets, which are peculiarly indestructible, should especially be looked for.

*Treatment.*—No medicinal treatment avails either to cause the death of hydatids or to arrest their growth. For the cure of the disease we must look to local measures only; and these consist mainly in the evacuation of the contents of the cysts. The puncture of the cyst with a bistoury, or a trocar and cannula sufficiently large to admit of the escape of the cystic progeny of the parent hydatid, is a procedure which has been largely adopted. It is obvious, however, that it can only be employed with safety when the cyst is adherent to the abdominal parietes, and the escape of the contents into the peritoneal cavity thus prevented. It can only be justifiably had recourse to, therefore, when the cyst has undergone inflammation or suppuration and has consequently got united with the surface over it; or after measures have been taken to ensure the formation of adhesions. Among methods which may be adopted to effect this object are: first, incision through the abdominal parietes until the cyst is exposed; second, the gradual destruction by caustic of a limited area of the abdominal walls down to the parietal peritoneum over the intended seat of operation; and, third, Trousseau's method of multiple acupuncture. In all such cases it is essential that the patient should be kept at rest, and the abdominal wall in close apposition with the subjacent cyst-wall by means of pressure, in order to ensure the formation of adhesions and their maintenance when formed.

A safer plan for evacuating the contents of those cysts in which suppuration has not yet occurred, is that which was strongly recommended some years since by Moissenet, and has since been successfully

employed in this country, and especially in the Middlesex Hospital by Drs. Greenhow and Murchison. It consists in the employment of an exceedingly fine trocar and cannula. The minute puncture made by this instrument rarely permits, even if no adhesions be present, of the escape of any appreciable quantity of the hydatid fluid into the peritoneal cavity, and is rarely, therefore, followed by grave peritoneal complications. In order, however, to guard against such accidents, it is well to select some prominent and central portion of the hydatid protuberance for puncture, to refrain from removing the whole of the contents at one operation, and after the operation to keep the patient at perfect rest and the punctured parts in close apposition by means of a compress and bandage. It is further desirable to preclude the entrance of atmospheric air, and for this reason also, if the aspirator be not employed, to be content with the partial evacuation of the cyst. In consequence of the operation the hydatid collapses, and falls away from the walls of the adventitious cyst in which it is contained. The space thus formed becomes filled, to a greater or less extent, with serous exudation which soon gets turbid; and the hydatid, bathed in the unwonted fluid, generally soon perishes. The cyst, shortly after paracentesis, may become nearly as tense as it was originally; but generally it begins to shrink again before long, and then gradually undergoes cure. The operation may not need to be repeated. Occasionally it fails to have any curative effect, even after having been several times performed. Another method of treatment has been recommended by Dr. Althaus, and successfully practised by Dr. Fagge and Mr. Durham. The details are furnished by Dr. Fagge in the following words:—‘Two electrolytic needles are passed into the tumour one or two inches apart, they are then attached to two metallic wires, both connected with the negative pole of a battery of ten cells. A moistened sponge forms the termination of the positive pole, and is placed on the patient’s skin at a little distance from the point of entrance of the needles. Its position is changed from time to time during the operation. The current is allowed to pass for about ten minutes. At the end of this time the needles are gently withdrawn and the seats of puncture covered with adhesive plaster.’ The above operation is often attended with some escape of fluid into the abdominal cavity, and some rise of temperature with other febrile symptoms. And as with simple paracentesis, so here, the immediate effects are not always obvious. The operation may need to be repeated. It has been recommended by some, that after the evacuation of more or less of the contents of the cyst, a solution of iodine, perchloride of iron, bile or some other antiseptic or parasiticidal fluid should be injected; and this practice has in some cases been successful. It is obvious, however, that the injection of irritating fluids is apt to induce inflammation and suppuration, which are in themselves very undesirable; and it is at least doubtful whether the death of the parasite is more surely attained by this procedure than it is by the simple evacuation of the fluid contents. If unfortunately peritoneal inflammation ensue, it must be combated by appropriate treatment. If suppuration of the cyst take place (and this is an accident for which we must be prepared), it will be also necessary to

accommodate our treatment to the altered condition of things. But especially the local treatment will need some modification. It will then at all events be desirable, so soon as we are satisfied that the cyst is adherent, that a free opening be made, and the contents, inclusive of the hydatid cysts, freely evacuated. Whether, however, that opening should be made with the trocar and cannula or the knife; or whether it should be allowed to close or be kept open; and in the latter case whether the contents should be allowed to escape by means of a drainage-tube or not; or whether the cavity should be washed out with some disinfectant solution; are points on which it is difficult to express oneself absolutely. The exigencies of cases as they arise necessarily call for modifications in the details of treatment. It is needless to discuss the treatment of the numerous other accidents and complications which are apt to manifest themselves during the course of hydatid disease.

### VIII. FATTY LIVER

*Causation.*—The deposition of fat-globules in the hepatic cells is not necessarily an indication of disease. It is frequently observed to a small extent in health; and sometimes indeed to a large extent in healthy persons who lead sedentary lives, or feed largely, especially those whose diet comprises an excess of fatty matter, or who have a tendency to obesity. That abundant deposition of fat, however, which constitutes what is meant by 'fatty liver,' is usually associated with various morbid states either of the system or of the liver itself. Among the former of these we may enumerate chronic alcoholism, heart disease, malignant cachexia, and especially pulmonary phthisis; among the latter cirrhosis, lardaceous degeneration, and the indurated condition which supervenes on chronic cardiac or pulmonary affections.

*Morbid anatomy.*—In the early stage fat-globules of small size are found scattered in the substance of the hepatic cells; at a later period many of the globules have enlarged, partly by coalescence, partly by fresh deposition, and may then considerably exceed in size the nuclei around which they cluster; at a still later period complete coalescence takes place, and the cells, distended with their oily contents, assume very much the appearance of the cells of adipose tissue. The deposition of fat always commences at the periphery of the hepatic lobules, and is very often limited to that part; and even when the change becomes universal it is still this outer zone which chiefly suffers. The presence of fat in any abundance renders the affected portion of the liver coarse, soft, dull, and opaque—the yellowness due to bile and the redness due to blood alike disappearing in a greater or less degree. Further, the tissue often becomes distinctly greasy, the fat adhering to the knife and fingers. It often happens in cirrhosis that the isolated nodules of hepatic substance are loaded with oil. In lardaceous change scattered patches of hepatic tissue are not unfrequently similarly affected. In cardiac and chronic lung disease the deposition is mostly

limited to the peripheral parts of lobules ; and indeed it is owing mainly to the contrast between the outer fatty and anæmic zones and the central deeply congested area, that the term 'nutmeg' has been applied to this form of hepatic affection. It is not uncommon to find the fatty and the congested regions of the lobules separated from one another by a line of deep jaundice. In the fatty liver of phthisis and other wasting diseases, the fatty accumulation may still be mainly peripheral, and the liver may consequently present something of the nutmeg character ; but not unfrequently the organ is pretty generally involved. Under these circumstances it presents a nearly uniform pallor, dulness of aspect, and softness, and its bulk is generally very largely increased. The enlargement of the fatty liver is as nearly as possible uniform. The fat consists mainly of olein and margarin, with traces of cholesterine. Its amount varies ; in extreme cases from 43 to 45 per cent. of the hepatic substance has been found to consist of fat, and indeed after removal of the water Frerichs has found no less than 78 per cent. of the residue to be fat.

*Symptoms.*—It is natural to believe that excessive accumulation of fat in the liver would seriously affect the functions of that organ ; and many different symptoms have been ascribed to it. We are bound, however, to confess that we have never met with a case in which hepatic or other derangement has been clearly attributable to it. And, indeed, it must not be forgotten that fatty accumulation is frequently associated with structural changes in the liver ; and that when under such circumstances hepatic symptoms are present, they are probably referrible to these associated lesions. The enlargement due to fatty deposition in the liver may often be recognised during life, and occasionally the augmented bulk of the organ produces fulness, weight, and uneasiness in the side.

*Treatment.*—When fatty liver depends on actual disease, it is essentially by treating the disease that we must hope to remove the hepatic accumulation. When we have reason to believe that enlargement of the liver, in persons who are fairly healthy, is due to fatty deposit, our treatment must be guided by our knowledge of their habits and tendencies, and must necessarily be mainly hygienic. It is very seldom, however, that we shall be called upon to make fatty liver a distinct object of medical treatment.

---

## IX. LARDACEOUS LIVER

*Causation.*—This affection is secondary to those morbid conditions of the system in which general lardaceous disease takes its origin : especially chronic phthisis, tertiary syphilis, caries of bone, and other conditions attended with prolonged suppuration.

*Morbid anatomy.*—The lardaceous change takes place first, according to Rindfleisch, in what he terms the arterial zone of the hepatic lobules, that is, midway between the centre and periphery, implicating both the minute arteries and capillaries of the part and the hepatic cells. But soon the morbid process extends to the central portions of the lobules, and

after a time the periphery becomes equally involved. The change is attended : with great thickening of the affected vessels, and the acquisition by them of a peculiar homogeneous pellucid character ; and with considerable enlargement of the hepatic cells, which lose all trace of granules, bile-pigment and nucleus, and become irregular or botryoidal vitreous-looking lumps which after a while break down into irregular fragments. The lardaceous liver, like the fatty, undergoes uniform enlargement in all its dimensions. It becomes smooth, heavy, and of somewhat doughy consistence ; and, if uniformly affected, presents a remarkably homogeneous sectional surface, of a greyish tint, with a peculiar glistening, or rather, perhaps, semi-translucent aspect, which has some resemblance to that of bees'-wax. It is equally free from biliary and vascular congestion, and from moisture. The lardaceous change is not unfrequently associated with fatty deposit, sometimes with cirrhosis, sometimes with syphilitic disease.

The size which the lardaceous liver may reach is almost unlimited. It has been met with weighing from ten to fifteen pounds. Its enlargement, however, is a slow process, and may go on for years.

*Symptoms.*—The circumstances which in combination justify the diagnosis of this affection are the slow but continuous uniform enlargement of the liver, without pain or obvious hepatic symptoms ; the long continuance of some one of those morbid conditions which we know to be conducive to lardaceous degeneration ; and the coetaneous enlargement of the spleen, and involvement of the kidneys. There is no doubt that patients with lardaceous liver manifest, as a rule, marked cachectic symptoms ; but there is little evidence to show that these are dependent in any peculiar degree upon the hepatic disease. It is true that a slight icteroid tinge occasionally manifests itself after a while, and that the bile in the gall-bladder and ducts is usually pale and watery ; but, on the other hand, there is never obvious pain in the region of the liver, never deep jaundice, rarely ascites, and (beyond the occasional presence of bile-pigment in the urine) nothing in that secretion distinctly to indicate impairment of hepatic function. The greater number of cases in which lardaceous disease manifests itself no doubt end fatally ; but there is reason to believe with Frerichs that, if the change be not far advanced, the arrest of the morbid process upon which it is dependent may be followed by the restoration of the lardaceous organs to health.

The *treatment* of lardaceous degeneration merges in the treatment of the disease which produces it.

---

## X. GALL-STONES

Very little of practical importance is as yet known with respect to the variations in quality and quantity of the bile, and the influence of these variations on the action of the bowels, the assimilation of alimentary matters and the general health. We know, no doubt, that when the bile

which enters the duodenum is deficient in quantity, fatty matters are imperfectly assimilated, the evacuations are fetid, and the bowels usually constipated; and we have reason to believe that, when there is an excessive discharge of bile, bilious diarrhœa and vomiting may be excited; but, on the other hand, we know that in many diseases, whether of the liver itself or of the general organism, the bile is found post mortem deviating widely from its normal condition, and yet there have been no symptoms during life which could be distinctly referred to this deviation. There is one abnormal condition of the bile, however, of great practical interest, which reveals itself to us, not directly by any of the consequences just enumerated, but by the formation of concretions which bring with them special symptoms and special dangers.

*Causation.*—The origin of gall-stones is obscure. It is easy, of course, to understand their increase of size by the accretion of additional solid matter; but it is not generally easy to determine the cause of the first step in their development, namely, the formation of a nucleus. In some rare cases this has been found to be a fragment of a needle, a dead entozoon, a small blood-clot, or (according to Dr. Thudichum) portions of the epithelial lining of the gall-ducts. In the majority of cases it consists of a mass of concreted biliary colouring matter. Concentration and stagnation of bile have doubtless some influence over the production of gall-stones, as is shown by their much more frequent formation in the gall-bladder than in the hepatic ducts, and probably also by their comparative frequency in cases of carcinoma, and other organic diseases of the liver. It is not clear that the tendency to biliary calculi is inherited, or that it is ever traceable to any dyscrasia, notwithstanding the statements which are made to the effect that it is generally associated with gout, renal calculi, or other maladies. On the other hand, we know that gall-stones occur much more frequently in women than in men, and chiefly in persons above the age of thirty. They are met with, however, not unfrequently at earlier periods of life, and occasionally even in infancy. There is reason to believe that they specially affect persons of sedentary habits. The influence of diet is unknown.

*Morbid anatomy.*—Gall-stones vary in size from mere granules up to masses moulded to the form of the gall-bladder, and measuring three or four inches in length, from one to one and a half inches thick, and weighing between one and two ounces. When they are minute (less in size, say, than a poppy-seed), they are usually spoken of as biliary gravel. Gall-stones may be solitary; but they are much more frequently multiple, and, indeed, many have been found at one and the same time scattered throughout the biliary ducts, and several hundreds in the gall-bladder. When occupying the latter cavity their size has necessarily some relation to their number; at all events, when they are very numerous, they cannot possibly be large; whereas solitary calculi, and calculi occurring in groups of two or three, often attain considerable dimensions. The forms which they assume depend mainly on their relations, during growth, to the surrounding parts. In the commencement they may be rounded or amorphous

accumulations of biliary colouring matter, or even rhomboidal tablets of cholesterine. But with increase of size some modification takes place. They may acquire a branched or coral-like form in the smaller bile-ducts; in the larger ducts or in the gall-bladder they may either form roundish masses, or accommodate their general shape to that of the cavity which contains them; but when, in the gall-bladder, the simultaneous development of many calculi takes place, they mutually interfere with each other's growth, and, instead of assuming a globular form, become polyhedral or faceted, or flattened one against the other. In this manner the bladder may get uniformly distended with a pyriform mass of closely-packed, mutually-fitting gall-stones; and, indeed, it generally happens that, when its cavity appears to be occupied by a single large calculus, this consists of at least two or three well-articulated but distinct masses.

Gall-stones are usually smooth, but sometimes granular or tuberculated, and vary in colour from milk-white, through yellow or brown, to deep reddish- or greenish-black. Their specific gravity ranges between .8 and 1.15; they are as a rule, however, heavier than water, and sink in it, excepting when they have undergone desiccation. In some cases they are so soft and friable as readily to fall to powder between the finger and thumb; and generally they are sufficiently soft to admit of being readily crushed into irregular fragments, or of being cut with a knife. They are usually soapy or greasy to the touch. As to their general structure, they consist sometimes of a simple tuberculated accumulation of pigmentary matter, sometimes of a nearly homogeneous waxy mass. In most cases three regions may be recognised:—namely, a central nucleus, which, as has already been stated, is mostly pigmentary and often irregular in form and shrunken; a zone of variable thickness around this, which is more or less homogeneous in texture, but marked with radial lines; and a cortical lamina, also of variable thickness, which is usually concentrically striated. These several regions are further characterised by differences of colour.

The chief constituent of gall-stones is cholesterine, and this forms on the average from 70 to 80 per cent. of the entire mass; but in addition, biliary colouring matter, biliary acids, and lime are found in various proportions. Other ingredients are so rare or so small in quantity as scarcely, from a clinical point of view, to be worth consideration. They are chiefly the fatty acids, uric acid, earthy phosphates, alkaline salts, and mucus. Calculi consist sometimes almost entirely of pigmentary matter, sometimes mainly of carbonate of lime with some admixture of phosphate, and sometimes of pure cholesterine. Moreover, the different laminae often differ in composition, the outer shell of large calculi frequently presenting an excess of earthy salts. Biliary gravel and calculi, consisting of colouring matter, are formed mainly in the biliary passages, whereas ordinary laminated calculi with abundant cholesterine in their composition arise in the gall-bladder almost exclusively. Indeed, there is reason to believe that their cholesterine is derived mainly from the secretion of the mucous lining of the gall-bladder, and scarcely, if at all, from the bile itself.

The consequences of biliary calculi are various. In many cases they slowly grow in the gall-bladder, until, moulded to its shape, they entirely fill it; when probably the bladder contracts upon them, ceases to perform its proper functions, and becomes merely the capsule of what then probably proves to be an inert mass. Sometimes the presence of these bodies irritates the mucous membrane of the bladder into inflammation, and, it may be, into suppuration and ulceration. Slight attacks of inflammation doubtless arise occasionally and subside again without further result. But when the inflammation is of a more intense character the cavity of the bladder may be converted into an abscess which discharges itself either *per vias naturales*, or by some abnormal channel; or its walls may become generally thickened, pulpy, and deeply congested; or at some point or other be fretted by its contained calculi into an ulcer which, gradually eating its way through the parietes (then probably glued to some neighbouring part), forms a sinus or diverticulum which, like the abscess, may open in one of several directions. The most common routes are externally through the abdominal walls, into the duodenum, and into the transverse colon. But the opening may also take place into the stomach, peritoneum, pleura, or lung. In many cases a gall-stone becomes dislodged, and slips into the cystic duct, whence it may pass slowly onwards until it reaches the duodenum. The duration of this process is very variable; in some cases it is over in a few hours, more frequently it occupies several days. The stone generally travels by fits and starts, and may be either temporarily or permanently arrested in any part of the channel along which it passes. If arrested in the cystic duct, it probably leads to its complete closure and to the enforced disuse of the gall-bladder, which may then either shrivel away or dilate into a mucous or serous cyst; if arrested in the common duct, it probably sooner or later obstructs the flow of bile, which then accumulates in the gall-bladder and ducts ramifying in the liver, and distends them. Further, in either of these situations, the stone may fret the surface against which it lies, and cause ulceration and possibly perforation, and thus lead to the formation of a local abscess, or to general peritonitis, or to some abnormal communication with the duodenum, colon, or portal vein. Gall-stones in the hepatic ducts are also apt to find their way into the duodenum, and occasionally cause ulceration, and perforation of the ducts in which they lie, with one or other of the several later consequences just considered. When once a gall-stone has descended, other stones, if they exist, are apt to follow; and moreover their passage is generally more readily and speedily effected than that of their pioneer.

*Symptoms and progress.*—The presence of gall-stones in the bladder or hepatic ducts does not necessarily cause symptoms, and in a large number of cases is from first to last unattended with symptoms. Gall-stones may, however, occasionally be recognised, in consequence of forming an irregular, hard, and sometimes crepitating lump in the situation of the gall-bladder. When their presence excites inflammation, we may look for tenderness, pain and fulness, in the same neighbourhood, together

with febrile disturbance. The pain is sometimes intense and paroxysmal, and lasts for months or years; and may be associated with so much gastro-intestinal disturbance, and progressive debility and emaciation, as to suggest the presence of malignant disease. But, unless any more distinctive phenomena arise, the exact nature of the affection can scarcely be diagnosed positively. Such phenomena are: the formation of an abscess superficial to the bladder in the abdominal parietes, and the ultimate escape of gall-stones with the other contents of the abscess; and the discharge of gall-stones through an ulcerated opening into the duodenum or colon, and their escape with the fæces, or their arrest in the small intestine, followed by enteritic symptoms. It must not be forgotten, however, that each of these phenomena may arise without having been preceded by any clear indications of inflammation of the gall-bladder.

The symptoms most characteristic of the presence of gall-stones are those which depend on their dislodgment and subsequent passage along the cystic and common ducts. They resemble in many important respects those due to the transit of a renal calculus along the ureter, and are mainly: severe pain, coming on suddenly, and lasting with irregular intermissions and exacerbations a few hours or several days; faintness, nausea, and vomiting; and the consequences of impediment to the escape of bile into the intestines. The pain (frequently termed hepatic colic) varies in intensity, situation, and quality. Sometimes it is comparatively slight, sometimes so severe that the patient writhes and cries out with agony; its character is aching, cutting, tearing, or burning, and it is generally attended with an unbearable sense of tightness, constriction or cramp. It is usually referred to the pit of the stomach or to the umbilicus, whence it extends to the back between the shoulders, to the chest or to the shoulder-tip, or down into the lower part of the abdomen. But its situation is often somewhat indefinite, and may be such as to simulate the passage of a stone along the ureter. There is seldom any material tenderness, and pressure sometimes affords relief from the pain. Hepatic colic is said to be further characterised by often coming on suddenly two or three hours after a meal, at the time when the passage of food along the duodenum excites the flow of bile from the gall-bladder and biliary passages. It often comes to a sudden end in consequence either of the slipping back of the stone into the gall-bladder, of its arrest at some point in the course of the cystic or common duct, or of its escape into the bowel. The faintness, nausea, and vomiting are not in necessary relation with the severity of the pain; the patient may be simply chilly, or he may have severe rigors; he may merely feel faint, or he may fall into a state of actual syncope or collapse, with cold and pallid surface, profuse perspirations, and imperceptible pulse; he may complain simply of nausea, or he may suffer from severe and protracted vomiting. The syncopic attack has proved fatal. A gall-stone may pass on from the bladder to the duodenum with all the above symptoms, and yet cause no material stoppage of bile. In a large number of cases, however, its presence in the common duct is followed by retention, which reveals itself by the vomit

(if it continue) ceasing to be bilious, by the stools acquiring a pale clay colour, by the urine in from twelve to twenty-four hours becoming tinged with bile, and by the development a little later of general jaundice. The supervention of jaundice, after such symptoms as have been detailed, is almost pathognomonic of the passage of a biliary calculus, or at all events of a foreign body, along the common duct. The diagnosis cannot, however, be regarded as positive unless the calculus be discharged per anum. And hence, in all cases of suspected hepatic colic, it is important to examine the fæces carefully from day to day. This should be done by diluting them with water, and passing them through a sieve with sufficiently small meshes to retain any small solid bodies which may be present in it. If the pain and other symptoms continue for any length of time, inflammation is likely to arise at the seat of disease; and tenderness and fulness may then come on, together with febrile disturbance. And even after the escape of the calculus, pain and fever, and even jaundice, may continue for some little time. The passage of one biliary calculus is often, if not generally, succeeded at irregular intervals by the passage of others—the later attacks, however, being as a rule both milder and of shorter duration than the first. This repetition of similar attacks is a further indication of the nature of the patient's malady. It is a point of some practical importance that when a stone lodged in the common duct becomes dislodged a renewal of hepatic colic usually takes place; and that hence the sudden recurrence of such an attack in a patient suffering from retention of bile is a hopeful sign. A calculus may completely occlude the common duct, certainly for a year, and then be discharged, with the restoration of the patient to health. On the other hand, death occasionally results, even before the coming on of jaundice, from rupture of the duct, and sudden intense peritonitis, or from profuse hemorrhage. The passage of biliary gravel, which has been sometimes discovered in the fæces in large quantities, and inflammation of the neck of the gall-bladder, may present many of the symptoms which attend the passage of calculi.

The consequences of the arrest of gall-stones in the small intestine have been described under the head of 'Intestinal Obstruction'; those of their long-continued or permanent retention in the common duct will be considered under that of 'Obstruction of the Hepatic Ducts.'

*Treatment.*—The general treatment of gall-stones is very unsatisfactory; we can neither dissolve them nor remove them; nor if they have once formed can we prevent them from becoming larger. And even as regards prophylaxis, all that can be said is that those whom we believe liable to them should eschew all such habits as seem likely to engender them. They should live wholesomely and abstemiously, and take a sufficiency of exercise daily. The habitual use of alkaline waters has been recommended, but the evidence in favour of their virtues is valueless. For the paroxysm of hepatic colic, our main reliance must be placed upon morphia or opium, given in sufficiently large doses, and sufficiently frequently, either by the mouth or hypodermically, to relieve the patient's sufferings. Belladonna has also been largely recommended, mainly with the object of relaxing

spasm; and so aiding the onward passage of the stone; but it is certainly not so beneficial in its effects as opium. The inhalation of chloroform, short of producing insensibility, often affords signal relief. To assuage the vomiting, Dr. Prout long ago recommended the use of copious draughts of warm water, containing from one to two drachms of carbonate of soda to the pint. This practice is still largely followed, and believed to be efficacious. In addition to these remedial measures, the warm bath, hot fomentations to the epigastrium, and counter-irritants may generally be employed with advantage. In cases of protracted complete obstruction, abdominal section may be performed (as has been done with success by Mr. Lawson Tate and others) and the stone be crushed through the walls of the occluded channel. Also, in appropriate cases the gall-bladder may be opened and its contents removed.

## XI. OBSTRUCTION OF THE HEPATIC DUCTS

*Causation.*—Obstruction of the hepatic ducts is an incident of common occurrence, and considerable importance, in a large number of the morbid conditions of the liver, which have already been discussed; it is also the most frequent cause of long-continued and intense jaundice, if not actually the most frequent cause of jaundice; and on these grounds demands special consideration. The causes of obstruction are, in some cases, inflammatory thickening of the mucous membrane of the ducts, or accumulation of inspissated mucus or other kinds of inflammatory exudation; in some the presence of stricture; in some the growth of polypoid tumours; in some the impaction of calculi or other foreign bodies. In other cases they are to be sought in inflammatory infiltration of the tissue of the lesser omentum or of Glisson's capsule, or in the development in these situations of syphilitic, carcinomatous, or other growths involving or compressing the ducts. Further, tumours springing from the stomach, pancreas, or neighbouring parts, and aneurysms, may press upon the common duct and obstruct its channel.

*Morbid anatomy.*—Obstruction may take place in any of the ducts at any part of their course; and the effects on the ducts behind the impediment, and on the liver-substance with which they are in relation, will be the same in kind wherever the obstruction is situated: the bile becomes arrested in its flow and altered in character, the implicated ducts undergo dilatation and other changes, and the liver-cells whose products they receive become jaundiced, fatty, and sometimes disintegrated.

If complete obstruction take place in the common duct, the dilatation of ducts which ensues is almost universal; the common duct not unfrequently attains the size of the duodenum, and the ducts ramifying throughout the liver acquire proportionably large dimensions. The condition of the gall-bladder under such circumstances varies; sometimes it shrinks or shrivels up, sometimes it retains pretty nearly its normal bulk, sometimes

it becomes, like the rest of the excretory apparatus, enormously distended. The consequences of obstruction, as respects the biliary fluid, are that it generally gets thin and watery, and at the same time of a dark green or brown colour. But it may also become turbid from admixture with mucus or pus; sabulous from the deposition of solid matter—pigment, or cholesteroline; coffee-ground like, from containing blood; or, when the bile ceases to form or to flow, transparent, colourless, and viscid. The last kind of fluid may be met with in the gall-bladder when, after closure of the cystic duct, it dilates (as occasionally happens) into a mucous cyst. The consequences, as regards the walls of the ducts, are also various. In most cases they thicken, but in some they become attenuated; in some inflammation with excess or modification of secretion takes place, in some ulcerative destruction. In the last case, perforation of the common duct may occur, with the development of an abscess in its vicinity, or rupture into the peritoneum; or more or less general destruction of the walls of the bile-ducts may ensue, with the formation in their place of irregular biliary channels, bounded by the eroded hepatic tissue, and communicating, it may be, with branches of the portal vein. Such channels may be converted into branching abscesses. The effects of obstruction on the liver generally are, in the first instance, gradual and uniform increase of bulk, which may be maintained for several months; and then gradual atrophy, the organ, however, not so much shrinking in all its dimensions as becoming wrinkled, thin, and flabby in consistence. The hepatic texture becomes soft, loose, œdematous (yielding on pressure a considerable quantity of thin greenish fluid), and jaundiced, or, before long, of a dark greenish hue. On microscopic examination, the hepatic cells are usually found deeply bile-stained, and often containing granular pigment and oil-globules. In some cases the cells after a time undergo degeneration; and all that remains of the hepatic texture may then be the framework of connective tissue, vessels, and the like, together with a greater or less abundance of free oil-globules, granules of precipitated pigment and cell-nuclei. The tissues, moreover, usually yield an abundance of leucine and tyrosine.

It has been assumed throughout the foregoing account that the obstruction is complete and permanent. But obstructions are often merely temporary, and, whether temporary or permanent, are not unfrequently incomplete; under either of which circumstances there will be more or less important modification in the progress and consequences of the secondary pathological lesions.

*Symptoms and progress.*—It is always important, for the sake both of prognosis and of treatment, but often quite impossible, to determine the exact cause of obstructive jaundice. Our diagnosis in each case must rest on a careful consideration of its history and progress and on a close investigation of the phenomena which come under our immediate observation. It is not, however, so much with this subject that we have now to deal as with the special symptomatic consequences of obstruction. These, which have already been pretty fully considered, may be divided mainly

into those dependent on absence of bile from the alvine evacuations, those due directly to the changes going on in the liver, and those arising from the accumulation of bile and effete matters in the blood.

The consequences of the absence of bile from the bowels have been sufficiently discussed.

Alteration in the bulk of the liver is a sign of considerable value. Its primary enlargement is indicated on the one hand by the gradual rise of the hepatic dulness into the chest, on the other hand by the gradual emergence of its lower edge from under the ribs and its extension for two or three inches below its normal level. If the gall-bladder also undergo distension, it may generally be recognised as an elastic or fluctuating rounded swelling coming out from beneath its accustomed notch. It is important, however, to bear in mind that, owing in great measure to the great length it is apt to attain under these circumstances, its apex may be displaced, even if the liver be little or not at all enlarged, far below or far to the right of its normal position; and further that, owing to its extreme mobility and tendency to retreat from the fingers, it often fails to yield any sense of fluctuation, and may be mistaken for a solid tumour springing from the liver or in its vicinity. In rare cases the distended common duct has itself been felt as a fluctuating tumour. When the later atrophic changes set in, the enlargement of the liver ceases, and the organ undergoes slow diminution in bulk; but this change reveals itself less by general shrinking than by diminution of thickness—the free edge often becoming peculiarly thin, so that, if the abdominal walls be flaccid and spare, it may often be readily grasped between the finger and thumb. Some degree of fulness, weight, tenderness, or pain is not unfrequent in the situation of the liver, during the progress of its enlargement; especially, of course, if inflammatory changes supervene.

The jaundice of complete obstruction is generally very intense. It first reveals itself by the presence of bile-pigment in the urine at the end of from twelve to thirty-six hours after bile has ceased to flow into the bowels. Yellowness of the conjunctivæ and skin usually supervenes in the course of the third day. If the obstruction continue, the intensity of the jaundice rapidly increases, and after a time tends to assume a greenish or brownish tint. The colour is liable to variations of intensity even when no discharge of bile into the bowels takes place, and by no means necessarily increases with the duration of the case; indeed, it not unfrequently undergoes manifest diminution during the later periods of the disease.

It is chiefly in jaundice from obstruction that we may look for the occurrence of many of those additional phenomena which have already been adverted to, such as yellow vision, itching, cutaneous eruptions, and petechial and other forms of hemorrhage; and it is with this alone that xanthoma has any connection. There is no necessary affection of the tongue or loss of appetite, and, as a rule, there is no elevation of temperature. Occasionally, however, even if there be no manifest inflammation or disorganisation, and independently maybe of the presence of pain, the patient suffers from time to time from an attack of rigors and of high

temperature, suggestive of the presence of suppuration or even of pyæmia. Such phenomena occur mainly in cases of obstruction due to the impaction of gall-stones.

It is almost needless to say that, in those cases in which the obstruction is temporary only, in those in which the obstruction of the main duct is, and remains, incomplete, and in those in which (as in hypertrophic cirrhosis) the impediment to the escape of bile involves some of the minuter tubes only, the symptoms will vary more or less widely from those which have just been detailed; especially the evacuations will probably still contain bile, the liver will undergo little or no enlargement, the jaundice will be slight, and the other symptoms which associate themselves with these conditions will be developed slightly or late, or not at all.

The duration of life in cases of jaundice with complete obstruction varies a good deal. In some the patient dies in the course of a few weeks; in some he survives for periods varying between six and twelve months; while occasionally life is prolonged to two, three, or more years. The causes of death also are various. It is due sometimes to rupture of the hepatic or common duct, or of the gall bladder, with consequent peritonitis; sometimes to the supervention of hepatic inflammation with suppuration and some one or other of their results; sometimes to intestinal or other hemorrhage; sometimes to so-called 'biliary toxæmia'; most frequently, however, it results from gradually increasing emaciation and debility. Further, patients enfeebled by this disease are apt to be attacked with pneumonia, dysentery, dropsy, or other complications, and to be thus carried off. In some cases recovery takes place even after complete obstruction has lasted for a considerable length of time; the indications of this event being the reappearance of bile in the fæces, the gradual disappearance of pigment from the skin and urine, and in association therewith general improvement in the patient's health.

*Treatment.*—In the treatment of jaundice from obstruction our first object should of course be to remove the mechanical obstacle to the escape of bile from the liver. This, however, can never be effected but by indirect measures, and in a large proportion of cases never effected at all. But in reference to this subject we must refer the reader to those articles which deal with the various conditions to which obstruction may be due. The question we have here specially to consider is—How shall the jaundice and the consequences it entails be best treated? Unfortunately, we can do little, and that little is mainly hygienic. The patient's bowels should be regulated if necessary by mild laxatives; the functions of the kidneys and of the skin (by which emunctories bile is now almost solely eliminated) should be promoted by the use of diluents, diuretics, warm clothing, and warm baths with rubbing or shampooing; his appetite should be sustained and his gastric digestion improved, if need be, by vegetable tonics or stomachics, with which the carbonates of the alkalies may often be beneficially combined; his general health should be maintained, partly by the exhibition of vegetable tonics and iron, partly by the habitual use of nutritious unstimulating food from which fatty matters

and alcohol are as far as possible excluded, partly by attention to hygienic conditions, more especially to warm clothing, the avoidance of chills or sudden vicissitudes of temperature, change of scene, moderate exercise and early hours. Of particular remedies it may be observed that Frerichs recommends lemon-juice as a valuable diuretic in these cases, and that Dr. G. Harley advocates the use of inspissated ox-gall in gelatine capsules to be given in doses of from five to ten grains two or three hours after each meal. When complications arise (gastric catarrh, diarrhoea, hemorrhage, or head-symptoms) they will probably need each its appropriate treatment. In those cases in which the gall-bladder becomes excessively distended, the question as to the propriety of puncturing it may arise. The operation is obviously one not to be lightly entertained, or to be performed without the most ample precautions.

## XII. JAUNDICE WITHOUT OBVIOUS OBSTRUCTION OF DUCTS

*Causation.*—The varieties of jaundice here referred to are more particularly those which occur in the specific febrile disorders, such as yellow fever, ague, relapsing fever, and pyæmia. It is possible, too, that under the same head must be included the jaundice which occasionally attends pneumonia, rheumatism, snake-bites, phosphorus-poisoning, and those other morbid conditions of the liver in which the secreting cells are directly involved. The jaundice which is said to arise under the influence of strong mental disturbance, and that of new-born babes, may possibly also be placed in the same class. It must be remarked, however, that there is still considerable uncertainty in respect of the intimate pathology of the jaundice attending these various affections; it is very probable that obstruction of the smaller ducts, or, as Virchow holds, catarrhal obstruction of the intestinal portion of the common duct, may eventually prove to be the cause of jaundice in some of them; there seems little doubt that in others it is actually due to changes going on in the colouring matter of the blood; and it is possible that occasionally it may be the consequence, as Frerichs holds, of an abnormal diffusion of bile, arising in some alteration in the supply of blood to the liver, and defective metamorphosis or consumption of bile in the blood; or, as Dr. Murchison believes, of excessive, reabsorption of bile with or without excessive secretion.

*Morbid anatomy.*—In most of the cases here referred to the liver is found post mortem to be pale and anæmic, and soft or flabby, and the hepatic cells either normal, or, as in phosphorus-poisoning, highly granular or studded with droplets of oil; in some the generally pallid tissue presents patches of still more marked pallor, which are often separated from the surrounding parts by wide but irregular zones of slight congestion. The appearances, as a rule, are certainly not very striking, and scarcely indicative of serious hepatic disease.

*Symptoms.*—The jaundice is almost without exception very slight; it creeps on gradually; it does not attain any intensity in the skin; and the urine is scarcely if at all tinted with biliary pigment. Moreover, the motions almost always still contain bile. There is no doubt that in many of these cases the symptoms which the patient presents are extremely grave. Yet there is no good reason to believe that as a rule they are due in any important degree to the hepatic disorder; for while the grave symptoms are usually such as characterise the disease which the jaundice complicates, those cases in which jaundice appears are not generally more serious than those from which it is absent, and the jaundice does not as a rule bring with it any specific symptoms.

*Treatment.*—The forms of jaundice now under consideration seldom call for special treatment. Their presence, however, may furnish a hint as to the desirability of employing laxatives, and promoting the action of the skin and kidneys.

### XIII. MALIGNANT JAUNDICE (*Yellow Atrophy of the Liver*)

*Definition.*—There is one form of disease in which jaundice is associated with a remarkable group of symptoms, which for convenience, if not on other grounds, may be separated from the cases just considered; it is that which is sometimes termed ‘malignant jaundice,’ and to which Rokitansky has given the name of ‘yellow atrophy of the liver.’

*Causation.*—Cases of malignant jaundice have been observed chiefly in adults, and in women more frequently than men. But children are now and then attacked with it. We have seen a typical example in a child two and a half years old. Moreover, in a large proportion of cases, the patient has been attacked during pregnancy. It is also a remarkable fact that the onset of the disease appears to have often been determined by some sudden and intense mental emotion. Among other assigned causes may be enumerated syphilis, typhus, and miasm.

*Symptoms and progress.*—Malignant jaundice frequently comes on without premonitory signs; but in a considerable number of cases it is preceded for a few days, or even a few weeks, by slight gastro-intestinal catarrh, with which probably, sooner or later, some degree of jaundice is associated. Among the earliest specific symptoms are vomiting, especially the vomiting of coffee-ground fluid due to gastric hemorrhage, intense headache, irritability, and restlessness. To these soon succeeds delirium, which is sometimes low and muttering, sometimes noisy, and frequently violent and maniacal. The patient’s manner is agitated, his limbs are generally tremulous, and in a large proportion of cases convulsions soon come on. These vary in character; may be general or local; and may present the features of simple rigors, or assume an epileptoid or tetanic form. After a short time, the condition of delirium or convulsion passes into one of quietness and stupor, which gradually deepens into profound coma, usually attended with dilated inactive pupils, and stertorous

breathing. But besides the remarkable combination and sequence of symptoms here enumerated, other phenomena present themselves which are of considerable significance and importance for diagnosis. The pulse during the earlier period of the disease, or that of excitement, is characterised by remarkable and sudden variations in frequency, but is generally abnormally quick; with the supervention of coma, however, it gets more uniformly rapid, and at the same time more and more feeble, until probably it can be no longer felt at the wrist. The tongue soon becomes coated, and generally before long assumes the typhoid character; it gets dry and brown or black, and sordes accumulate upon the teeth. There is often some uneasiness and tenderness in the hepatic region, and in addition gradual diminution in the area of hepatic dulness can often be detected by careful examination. The bowels usually are confined; and the motions passed in the course of the disease present a gradual diminution, and at length, may be, total absence of biliary colour. The urine probably is secreted in normal quantity and acid; but it becomes jaundiced in a greater or less degree, urea and phosphate of lime diminish, and sometimes disappear, to be replaced by leucine, tyrosine, and extractive matters, which, when the urine cools, tend to form a greenish-yellow sediment. The skin is usually cool and dry. The jaundice, which sometimes precedes, sometimes follows, sometimes appears simultaneously with, the other initial symptoms of the disease, increases in depth with the duration of the malady, but rarely, if ever, attains a high degree of intensity. Two features of striking importance are, the total absence of febrile temperature, and a general tendency to hemorrhage. The latter shows itself by hæmatemesis, the appearance of petechiæ and bruise-like extravasations beneath the skin, or discharges of blood from the nose, bowels, or other mucous surfaces.

The most characteristic phenomena in the clinical aspect of malignant jaundice are, in combination, slight jaundice, grave cerebral disturbance, hemorrhage from and into various organs and tissues, profound change in the composition of the urine, absence of fever, and an almost invariably fatal issue. Death may supervene within twelve or twenty-four hours, but generally occurs between the second and fifth day, and is rarely delayed beyond a week.

*Morbid anatomy.*—In all typical cases of the disease the post-mortem conditions are remarkable and characteristic. The most obvious change is in the liver. This may be of natural size, but is usually shrunk to half or even one-third of its normal bulk—its surface then being wrinkled and flabby. On section it is found to be of a nearly uniform pale yellow colour, with little or no indication of the constituent lobules, or evidence of vascular injection. Frerichs says that in some cases the lobules are separated from one another by a dirty greyish-yellow substance. The bile-ducts and gall-bladder usually contain either colourless mucus, or a thin fluid, only very slightly tinged with bile. On microscopic examination, the hepatic cells are found to have disappeared more or less completely—in some cases not one is discoverable; and in their place may be

observed either simple granular matter, or this intermingled with oil globules and precipitated bile-pigment. Leucine and tyrosine also may be recognised in the hepatic substance and hepatic veins. There is usually enlargement of the spleen. The only other morbid phenomena of importance are: occasionally fatty change of the glandular epithelium of the kidneys; extravasations of blood (usually petechial) beneath the surface of the peritoneum, pleuræ, and pericardium, in connection with the gastro-intestinal and other mucous membranes, and occasionally in the substance of the lungs, liver, spleen, and kidneys; and the presence in the blood (which does not as a rule display any change visible to the naked eye) of large quantities of leucine and urea.

The nature of the malady under consideration is by no means satisfactorily established. By some it is regarded as a primary disease of the liver. Frerichs, who (following Bright) takes this view, looks upon it as a parenchymatous inflammation of the organ, attended with little exudation, but with obstruction to the passage of blood through the vascular network at the periphery of the lobules, and consequent degeneration and death of the hepatic cells. According to this view, the jaundice and other characteristic symptoms of the disease are secondary to the hepatic lesion. Some, on the other hand, look upon the hepatic affection as the consequence of some general blood-disease, due either to the absorption of some noxious chemical substance, or to the presence of a poison of organic origin having some affinity with those of the infectious fevers, or of pyæmia. In the latter point of view some of the graver symptoms would be referrible to the primary disease of which the hepatic disorder is a consequence; but others might still be attributable to the morbid condition of the liver. It would not be difficult to adduce plausible arguments either against or for either of these hypotheses. We may, however, point out that while, on the one hand, there is nothing in the clinical phenomena of these cases to indicate their inflammatory origin, there is, on the other hand, ample proof, from the occasional supervention of the symptoms of malignant jaundice in cases of occlusion of ducts, that extensive destruction of the secreting structure of the liver, with suppression of bile, is fully competent to induce all the phenomena of the disease under consideration. We must confess, indeed, that, while not quite committing ourselves to the inflammatory origin of the hepatic changes, we are disposed to regard the disease as primarily hepatic.

*Treatment.*—Nothing can well be less satisfactory than our knowledge in reference to the treatment of malignant jaundice. Active purgation has been recommended, especially in the early stage; it is difficult, however, to understand why. Again, those who look upon the disease as of inflammatory origin advocate the local abstraction of blood, and other antiphlogistic measures, during the inflammatory stage. But unfortunately this, if it exist at all, exists only during that preliminary period in which there is nothing to distinguish cases of malignant jaundice from cases of catarrhal affection of the biliary ducts. Considering that in this disease there is a large accumulation of effete matter in the blood, on

which it seems probable that some of the grave symptoms are dependent, there are grounds for the employment of diuretic and diaphoretic measures. In the absence of more obvious indications, we must either do nothing or treat the more prominent symptoms : that is, so far as we are able, check vomiting, arrest hemorrhage, overcome constipation, promote the action of the skin and kidneys, soothe during the stage of excitement, and during that of stupor and coma and failing strength employ counter-irritants and stimulants.

---

#### XIV. DISEASES OF THE PANCREAS

A. *Introductory remarks.*—Very little of clinical value is known about the diseases of the pancreas. This is due : partly to the comparatively small size and deep situation of the gland ; partly to the fact that its functions have much in common with those of the salivary and duodenal glands, and even with those of the liver itself ; but chiefly, perhaps, because it is rarely affected except secondarily or in association with diseases of neighbouring organs.

In reference to the diagnosis of pancreatic disease, we must recollect : that this organ is situated in front of the aorta and behind the stomach, deep in the epigastric region, and on the level of the first lumbar vertebra ; that any tumour which may be developed in it will be discoverable in this situation only (a situation, however, which may be equally affected by aneurysms of the aorta or cœliac axis, or by tumours involving the posterior wall of the stomach, or originating in the retro-peritoneal glands), and will probably be immovably fixed there ; and that any pain and tenderness which may attend its lesions will probably be referred to the depth of the epigastric region and to the back, in the situation of the upper lumbar and lower dorsal vertebræ. We must also recollect that the function of the organ is to secrete a large quantity of fluid, which differs little from ordinary saliva in either its chemical composition or its office, and is an important agent in the emulsification of fat, in the conversion of starch into dextrine and sugar, and in the reduction of albuminous matters into a form favourable for assimilation. It may therefore be reasonably believed that the retention or suppression of the pancreatic fluid will be attended with more or less serious impairment of nutrition ; and, if the food contain much starch or fat, with the unwonted appearance of starch or fat in the evacuations. The abundant discharge of fat by stool, indeed, has been not unfrequently noticed in cases in which the pancreas has been seriously diseased.

B. *Hyperæmia and inflammation.*—Of these conditions but little can be said. They are occasionally recognised post mortem, but for the most part in cases where no suspicion of pancreatic disease was entertained during life. *Abscesses* are sometimes discovered in the gland, and occasionally large abscesses ; but they are usually small and of pyæmic origin. *Catarrhal inflammation* of the duct is probably not uncommon

in connection with the same affection of the common hepatic duct, and may, like that, lead to temporary or even permanent obstruction. In chronic ulcer of the stomach the subjacent pancreas not unfrequently becomes implicated in the course of the extension of ulceration : and thus its eroded substance may after a time form the floor of the ulcer.

C. *Morbid growths*.—The pancreas is often the seat of such formations ; but they are rarely of primary origin within it. They are sometimes a consequence of the generalisation of malignant tumours, but are much more frequently due to extension of disease from the stomach, retro-peritoneal glands, or peritoneum. It is, however, in carcinoma of the pyloric extremity of the stomach that the pancreas most frequently becomes involved. Of the several varieties of malignant disease to which it is liable, scirrhus is the most common ; but the encephaloid, colloid, and melanotic forms have each been met with.

D. *Calculi* are occasionally discovered in the pancreatic ducts, and more especially in the principal duct. They have the same chemical and other characters as other salivary calculi—consisting mainly of phosphate of lime with some animal matter, and varying from minute granules up to the size of a filbert. When small they are sometimes present in vast numbers ; when large they are usually solitary, and more or less completely obstruct the duct in which they lie.

E. *Obstruction of the pancreatic ducts*.—When these channels get blocked up, whether by calculi or stricture, or in consequence of their compression by, or involvement in, malignant or other growths, the ducts behind undergo gradual dilatation from the accumulation of secretion within them. The chief enlargement occurs in the principal duct, which becomes elongated and tortuous, irregular in form, and sometimes sufficiently dilated to admit the finger. The secondary ducts also dilate, but in a less degree ; and the whole organ consequently increases in bulk, and on section appears at first sight to be made up of a congeries of cysts—the secreting tissue between them being more or less atrophied. Solitary cysts, apparently due to the dilatation of obstructed ducts of small size, are occasionally discovered in otherwise healthy glands. Their only pathological importance arises from the fact that they may, from their size and situation, be readily mistaken for tumours or cysts of much more serious import. They may attain the size of an orange.

F. *Symptoms and treatment*.—It would be a waste of time to discuss the diagnosis of the above lesions ; the special phenomena to be looked for as indicative of pancreatic disease have already been sufficiently considered ; and for the recognition of additional features special to each variety of lesion, the practitioner must be guided by his general knowledge of pathology and of the pathology of the pancreas. In the great majority of cases pancreatic disease will doubtless remain undetected during life.

It would be equally a waste of time to enter upon the discussion of the treatment of pancreatic affections.

## CHAP. VI.—DISEASES OF THE GENITO-URINARY ORGANS

### SECTION I.—DISEASES OF THE KIDNEYS

#### I. INTRODUCTORY REMARKS

##### *General Physiological and Pathological Considerations*

THE urinary organs comprise the kidneys, ureters, bladder and urethra. The diseases of all these parts are of high interest to the physician; but those of the kidneys and ureters come more especially under his observation and treatment, and it is mainly to them, therefore, that attention will be directed in the following pages.

The sole function of the kidney is to separate from the blood, in association with water, a number of effete, waste, and surplus matters which are constantly being added to the blood from various sources. But the urine, as it escapes from the urethra, contains in greater or less proportion certain additional matters (mucus and the like) which are yielded to it by the various mucous surfaces over which it passes, and by the glandular organs which open upon them.

The urine, thus constituted, varies in composition within wide limits, even in health. In disease, where the nutritive and destructive processes are variously modified, and where the functional activity of important organs is in different degrees diminished, impaired or exalted, the composition of this fluid undergoes still greater variations; and, indeed, there are some cases (as, for example, that of diabetes) in which, the kidneys remaining sound, the nature of the disease under which the patient labours is revealed almost solely by the peculiarities which the urine presents. But especially the composition of the urine is largely and importantly modified by diseases of the urinary organs, which tend on the one hand to impede the discharge from the blood of the proper urinary constituents, and on the other hand to add to the urine matters which are wholly foreign to its normal constitution. It is obvious, therefore, that the careful investigation of the urine may be expected to throw important light, not only on the varying processes connected with healthy nutrition, but also on the pathology of many of those morbid conditions in which the kidneys are not distinctly implicated, and above all on the nature of the diseases of the kidneys themselves, and of the several organs in relation with them.

But, again, when the urinary organs are the seat of disease, and oppose (as they then generally do) a more or less complete obstacle to the elimination of urea and other such products from the blood, it is clear that this fluid must soon become surcharged with effete and presumably

injurious matters of a specific kind, and that we must, therefore, expect specific morbid consequences sooner or later to ensue.

It is also clear that many diseases of these organs must be attended with both local and general indications and symptoms which are totally independent of the functional derangements which are associated with them : local phenomena, such as pain and tumour ; general phenomena, such as inflammatory fever and some forms of cachexia.

The morbid phenomena, therefore, which are associated with, and result from, diseases of the kidneys may be properly and conveniently divided : first, into those which are special to these organs, and depend directly on the impairment or perversion of their normal functions ; and, second, into those which in a certain sense are common to these and other similarly affected constituent portions of the body.

In accordance with the foregoing observations, we propose to give a brief account : first, of the composition of the urine in health and disease ; second, of the specific consequences of the retention of urea and other such matters in the blood ; and third, of the non-specific morbid phenomena which attend and characterise lesions of the urinary organs.

#### *A. Characters and Composition of the Urine*

The urine is a transparent, limpid, straw or amber coloured fluid, of saline taste, and for the most part of acid reaction, which deposits, on standing, a filmy cloud of mucus, and occasionally an opaque, reddish, powdery sediment. Its acidity increases for a few days with exposure to the air, and at the same time urates, uric acid, and oxalates are deposited. Then it undergoes putrefaction ; becomes alkaline and ammoniacal ; earthy matters, including crystals of triple phosphate, fall ; and bacteria and torulæ make their appearance in it.

The quantity passed in twenty-four hours fluctuates within wide limits : it may, however, be reckoned usually at between two and three pints in the adult, but may range from one to four pints. The specific gravity also presents a wide range : it commonly lies between 1015 and 1025, but temporarily may fall to 1005 or less, or rise to upwards of 1030. The acidity, which when the urine is emitted from the bladder is an almost unfailling characteristic of it, is liable to a good deal of variation of intensity ; and, indeed, as Sir. W. Roberts shows, that which is secreted an hour or two after meals is generally alkaline, although its alkalinity is commonly masked by its admixture in the bladder with acid urine already there or subsequently added to it. The acidity depends mainly on the presence of acid phosphates and urates, and in some degree also on traces of lactic, oxalic, and other acids.

The degree in which the specific gravity of urine exceeds that of distilled water depends on the solid matters (the special urinary constituents) contained in it. The proportion which these hold to the watery constituent may be approximately estimated, according to Trapp's formula, by doubling the last two figures of the number indicating the specific gravity. Thus 1000 parts of urine with a specific gravity of 1015 contain

30 parts of solids ; and 1000 parts of urine with a specific gravity of 1025 contain 50. Hence the amount of solid matter in healthy urine usually varies from three to five per cent. It is generally, however, far more important to know the actual amount of solid matter that is passed daily than the ratio which the solid matter holds to the very variable quantity of water with which it is mixed. This knowledge can be gained by collecting and mixing all the urine passed in the course of twenty-four hours, and then examining quantitatively a measured portion of its bulk, or, more readily, though less accurately, by the method above given.

The solid matters of the urine are very numerous ; and they vary largely, both in the relative proportions in which they are excreted and in their aggregate amount. The urea especially is remarkably modified by age, sex, diet, and other circumstances, so that the amount which may be taken as the average may be halved or doubled independently of any impairment of health. The following table is designed to show at a glance the relative proportions of the chief constituents contained in an average specimen of the urine of an adult, and the total quantities of each which might in such a case be discharged in twenty-four hours. The specific gravity is assumed to be 1025, and the temperature 32°.

Urinary constituents	Per-centage composition	Daily aggregate in grains
Water . . . . .	95·000	19000·0
Urea . . . . . $\text{CH}_4\text{N}_2\text{O}$	2·500	500·0
Uric acid . . . . . $\text{C}_5\text{H}_4\text{N}_4\text{O}_3$	·042	8·5
Kreatinine . . . . . $\text{C}_4\text{H}_7\text{N}_3\text{O}$	·075	15·0
Hippuric acid . . . . . $\text{HC}_9\text{H}_8\text{NO}_3$	·075	15·0
Pigment, mucus, } odorous matters, } Extractive . xanthine, &c. }	·600	120·0
Total organic matters . . . . .	3·292	658·5
Chlorine . . . . .	·500	100·0
Sulphuric acid . . . . .	·150	30·0
Phosphoric acid . . . . .	·250	50·0
Potash . . . . .	·175	35·0
Soda . . . . .	·600	120·0
Lime . . . . .	·018	3·5
Magnesia . . . . .	·015	3·0
Total fixed salts . . . . .	1·708	341·5
General total . . . . .	100·000	20000·0 or 45 $\frac{1}{3}$ oz.

The variations in the quality and quantity of the urine in health are so wide that it is often extremely difficult, and sometimes impossible, to be certain, from the examination of this fluid alone, whether it should be regarded as healthy or morbid. When matters are added to it which are wholly foreign to its composition, and cannot be ascribed to the influence of special articles of food or other substances which have been received into the blood, no doubt as to its morbid character can be entertained. Again, when, independently of external conditions and habits of life, the urine habitually deviates largely from the mean, whether in the direction

of excess or diminution, as regards either its total bulk or the amount of any of its more important constituents, no doubt as to its unhealthiness is possible. And again, when sediments form habitually, even though the sedimentary matters be normal constituents of the urine, and the chemical composition of the urine itself reveal no appreciable departure from health, the unhealthy condition of the secretion is indisputable.

In the following account of the urine, which is intended to be mainly pathological, and from which, therefore, some physiologically important constituents will be omitted, it will be convenient, after briefly adverting to the physical characters of morbid urine, to embody such physiological and chemical remarks in reference to its normal constituents as are necessary for a clear comprehension of the pathology of this excretion.

1. *Physical characters of morbid urine.*—The quantity of urine passed differs very largely in different diseases. In some general affections, as cholera and collapse (especially collapse connected with lesions of the abdominal organs), the urine is suppressed absolutely. In most febrile disorders, and in inflammations, it is diminished. In other cases on the contrary, as after hysterical paroxysms, in the condition known as diabetes insipidus, and especially in diabetes mellitus, it becomes profuse. Again, the urine is generally greatly diminished when acute nephritis is present; it may even be temporarily suppressed from this cause. On the other hand, in chronic renal disease it is often largely increased. Its discharge is occasionally arrested in consequence of obstructive disease of the ureters.

The amount of solid constituents present is not necessarily in relation with the quantity of urine voided; though no doubt generally, the more scanty the urine is, the higher is its specific gravity, and the larger the ratio which the solid matters hold to the water. But, on the other hand, in most febrile diseases there is an actual increase in the total nitrogenous constituents, even while there is a marked diminution in the total bulk of urine passed; and in the profuse urine of diabetes mellitus the quantity of solid matters excreted is so large that the specific gravity often rises to 1040, 1050, or 1060.

The urine in disease may have the same reactions as in health; or, on the other hand, it may be preternaturally acid, or neutral, or alkaline. Alkalinity of urine may be caused by the presence either of ammonia or of fixed alkalies. Ammonia is due to the decomposition of urea, and appears only after the urine has been secreted by the kidneys. It mostly appears in connection with chronic inflammation of the mucous lining of the bladder and other parts, and the discharge therefrom of morbid mucus. The persistence of alkalinity due to the fixed alkalies, if it be not dependent on peculiarities of diet or on medicine, is generally connected with affections characterised by anæmia and debility. Acidity may be recognised by the use of blue litmus paper, which becomes red under the influence of acids, and alkalinity by the employment of red litmus paper, which is rendered blue by alkalies, or of yellow turmeric paper, which becomes brown. If the alkalinity be due to ammonia, the test-paper changed under its influence returns to its original colour on being dried.

As regards colour, smell, and the presence of turbidity or sediment, all that we deem it necessary to say will be incorporated in our subsequent account of those urinary constituents to which severally these conditions are mainly due.

2. *Urea* ( $\text{CH}_4\text{N}_2\text{O}$ , or  $\text{CO}(\text{NH}_2)_2$ ).—This is by far the most abundant and important of the urinary solids. It is furnished by the destructive metamorphosis of the nitrogenous tissues of the body and elements of the food, and contains nearly the whole of the nitrogen which was originally incorporated with the substances from which it is derived. Its quantitative variations are so great during health that it is impossible, in a few words, to explain when and at what point such variations are to be regarded as morbid. Urea is almost always largely increased during the febrile stages of inflammatory and febrile disorders, and in diabetes. It should be observed, however, that the quantity of urea eliminated is not in direct relation with the intensity of fever. In some febrile diseases the urine contains no excess of urea; and generally when the curves representing the daily temperature and amount of urea are compared, the only correspondence between the two will be found in the early stages of the fever, and the longer the disease lasts the greater will be their disagreement. Urea being formed mainly in the liver, it is very probable that the amount of it eliminated is always largely influenced by the condition of the hepatic cells, and by the activity of the hepatic circulation. Thus in malignant jaundice it diminishes, and finally disappears wholly; in jaundice, the result of phosphorus-poisoning, its temporary increase is followed by marked diminution; and the same remark applies to the cases of simple jaundice and hepatic abscess; in obstruction from gall-stones (notably during the period of hepatic colic), and in the subsequent atrophy of the hepatic parenchyma, there is likewise a diminution. So also is it in the various forms of cirrhosis, and in chronic congestion of the liver. Again, urea is diminished in nephritis and other inflammatory or structural diseases of the kidneys, in anæmia, and starvation. Urea is a feeble base, and exceedingly soluble; and has, therefore, under ordinary circumstances, no visible influence over the condition of the urine. It forms no sediment, and cannot be detected in it except by chemical processes. Under the influence of the mucus of the bladder, and some other circumstances, it is readily converted, with the aid of water, into carbonate of ammonia. Urea crystallises in white silky needles, or transparent four-sided prisms, the ends of which are often formed by one or two inclined planes. Such crystals may often be obtained by evaporating a drop of urine (especially febrile urine) on a glass slide. If an excess of colourless nitric acid be added to urine concentrated by evaporation, the mixture, especially if cooled with ice, will become almost solid with crystals of nitrate of urea. These occur in rhombic prisms or plates which are colourless, have a silky lustre, and are arranged for the most part in rosettes or spheres. For the quantitative determination of urea various methods have been employed. The following are probably the best.

*a.*<sup>1</sup> With a solution of mercuric nitrate, urea forms a white gelatinous precipitate, containing one equivalent of urea to four equivalents of mercuric oxide. The determination of urea by Liebig's method is based on this reaction. A standard solution of mercuric nitrate is prepared of such a strength that ten cubic centimetres are equivalent to one gramme of urea. This is done by dissolving 71·5 grms. of pure mercury in nitric acid, and diluting with distilled water to one litre. Before urine is precipitated by this solution its phosphates must be removed by the addition of a mixture of one part of cold saturated solution of baric nitrate with two parts of a similar solution of baric hydrate. Further, if albumen be present, it must be separated by boiling and the addition of a few drops of acetic acid.

The process is thus performed :—Two volumes of urine (say 40 c.c.) are mixed with one volume (20 c.c.) of the baryta solution. After shaking well the mixture is poured on a dry filter, and 15 c.c. of the clear filtrate (equal to 10 c.c. of urine) removed to a small beaker. Mercurial solution is now slowly added from a burette so long as precipitation occurs. But to find the exact point when all the urea has been precipitated, it is necessary to employ some such indicator as sodic carbonate. Several drops of a solution of this salt are scattered over a white plate ; and by means of a glass rod a little of the mixture in the beaker is brought in contact with the soda. So long as there is any free urea present no change of colour takes place at the point of contact ; but as soon as the mercury is in excess, a yellow precipitate results. The moment, therefore, the yellow colour shows itself distinctly, enough mercuric solution has been added. To attain an accurate result, the experiment should be performed a second time. Supposing 19 c.c. of the mercuric nitrate were required by the 10 c.c. of urine, this would indicate a percentage of 1·9 urea in the urine. If, however, it should be found that more than 20 c.c. are needed, the urine for the second examination must be diluted by adding half as much water as the excess of mercuric nitrate solution employed above 20 c.c. Thus, if 30 c.c. were required in the first precipitation, the excess is 10 c.c. ; therefore, 5 c.c. must be added to the 10 c.c. of urine before the second precipitation. If, on the other hand, much less than 20 c.c. have been used, then for every 4 c.c. less than 20, ·1 c.c. must be deducted before calculating the percentage of urea.

*b.* A very easy method for the estimation of urea depends on the measurement of the nitrogen evolved when the urea is decomposed by a hypochlorite or hypobromite. Urea yields in this way all its nitrogen, less 8 per cent. Different apparatus are used ; but in all of them there are mechanical arrangements to bring about the gradual admixture of the urine with the test solution, and to collect the gas evolved. 5 c.c. of a 2 per cent. solution of urea yield about 37 c.c. of gas. The collecting tubes are generally graduated so as to express at once without calculation the percentage of urea present in the urine experimented upon. The volume of gas given by, say, 5 c.c. of a two per cent. solution of urea, which

<sup>1</sup> 1 gramme = 15·432348 grains = the weight of a cubic centimetre of distilled water at 39·2° F.

1 litre = 1000 cubic centimetres = 61·024 cubic inches = 35·2754 fluid ounces.

is about 37 c.c., is taken as indicating 2 per cent. of urea, and the collecting tube is graduated accordingly.

3. *Uric acid* ( $C_5H_4N_4O_3$ ) and *urates*.—Uric acid is derived from the same source as urea, and is liable to slight fluctuations in quantity under much the same circumstances as urea. It is readily decomposed by oxidising agents into several less complex substances, of which urea (to which it contributes the whole of its nitrogen) is the most important. It may, in fact, be regarded as representing a stage in the conversion of albuminous matter into urea. It is exceedingly insoluble in water, and hence, when free in the urine, forms a crystalline deposit. It is, however, generally combined with a base, especially ammonia or soda, and in this form is much more soluble, though still liable to form a sediment. The main interest, indeed, attaching to the presence of uric acid and urates in the urine resides in the fact of their tendency to be deposited, and to take part in the formation of gravel and calculi.

*Free uric acid* often falls during the acid fermentation taking place in urine which is kept; and, when met with in fresh urine, it is generally in consequence of the acid reaction of that fluid being excessive. It may be readily recognised by the character of its crystals. These may form reddish grains visible to the naked eye, but are generally microscopic objects. The forms which they assume are various, and depend largely on the quality of the urine in which they are found. They are generally lozenge-shaped or rhomboidal, with the angles more or less rounded, and vary in thickness, so as to form, on the one hand, mere films, on the other, short flattened cylinders, or prisms. When abundant they are often grouped together into stellate or variously shaped clusters. If any doubt as to the nature of the deposit exist, it may be set at rest by converting it into murexide. This may be done by placing a little of it in a porcelain dish, adding to it a drop or two of strong nitric acid, and heating the whole to dryness. If now, when the residue is cool, a rod dipped in caustic ammonia be applied to it, the beautiful purple colour characteristic of murexide, is developed.

*Urates*, comprising chiefly those of ammonia and soda, are often deposited in an amorphous condition, forming a powdery sediment which clings to the vessel, and which,

FIG. 75.—Uric acid and urates  $\times 500$ .

from its attraction for the colouring matter of the urine, varies in tint from a light fawn to pink. Like uric acid itself, they generally precipitate in acid urine, but, unlike uric acid, they mostly fall in concentrated urine, especially when it becomes cool. The formation of uratic sediments often occurs in the urine of healthy persons, especially in cold weather; it often, however, attends and indicates the presence of catarrh or other febrile states or derangements of the liver or other chylopoietic viscera. Amorphous urates are readily recognised by the fact that urine which is turbid from their presence becomes perfectly clear and transparent when boiled. Further, the addition of acids causes the formation of crystals of uric acid; and murexide may be developed by the method already indicated. Urate of soda is occasionally present in the shape of small globular concretions beset with conical spikes. These form in the urine while it is yet in the urinary cavities, and are liable to cause much irritation, and to lead to the development of calculi. They have been especially observed in the case of children suffering from febrile symptoms.

4. *Xanthine* ( $C_5H_4N_4O_2$ ) is a waxy, white, non-crystallisable substance almost insoluble in cold water. When heated with nitric acid it dissolves without evolving gas; and the residue left on evaporation acquires when heated with caustic potash a beautiful violet-red colour.

5. *Cystine* ( $C_3H_7NSO_2$ , or  $C_3H_5NSO_2$ ) contains 25.5 per cent. of sulphur. It is closely related chemically to taurine, and hence probably furnished by the liver. It is a neutral body, insoluble in water, and crystallises in hexagonal plates. It is dissolved by the mineral acids with decomposition, and by the caustic alkalies without. The best way

to obtain the characteristic crystals is to dissolve the cystine in a solution of ammonia and allow the solution to evaporate.

6. *Leucine* ( $C_6H_{13}NO_2$ ) and *tyrosine* ( $C_9H_{11}NO_3$ ).—These are formed under the same conditions and are generally associated together. Pure leucine occurs in white crystalline scales, has a fatty feel, and dissolves in water. In the impure state, as observed in urine it often assumes the form of roundish concentrically marked yellowish

FIG. 76.—Cystine  $\times 500$ .

bodies which have some resemblance to fat-globules. If a small portion of leucine be saturated with nitric acid and the mixture carefully evaporated to dryness, it leaves an almost transparent residue which turns yellow or brown on the addition of solution of caustic soda, and yields an oily drop when reheated. Tyrosine forms a white, silky, glistening mass, consisting of fine needle-like crystals, which are grouped in radiating clusters, and sometimes in dense globular masses. It gives a red coloration when

boiled with Millon's reagent; and a violet hue when gently warmed with sulphuric acid, and a drop of solution of perchloride of iron is added. The urine of patients suffering from yellow atrophy of the liver often deposits spontaneously a greenish-yellow sediment consisting of crystals of tyrosine, and on evaporation yields numerous crystals of the more soluble leucine.

7. *Colouring matters*.—The normal pigments of the urine are derived from the colouring matter of the blood, and, according to Schunck, are two in number. He names them respectively *urian* and *urianine*. They are of a dark yellow colour and syrupy consistence, have a high atomic constitution, and contain nitrogen. Their excess or deficiency has little special pathological importance. Another urinary pigment has been described by Dr. Thudichum under the name of *urochrome*. The pink colouring matter, however, termed *purpurine* or *uro-erythrine*, is a pathological product. Its chemical constitution and source have not been ascertained; but it is common in febrile and inflammatory affections and in cases of organic disease, especially of the liver, and has a remarkable affinity for uratic sediments, to which it clings and imparts its special tint. *Indican*, the peculiar body by whose decomposition indigo-blue and indigo-red are obtained, has been ascertained by Schunck to be a normal constituent of urine. It is to this source that the occasional presence of indigo-blue in decomposing and morbid urine appears to be due.

8. *Odorous matters*.—The peculiar smell of normal urine is due to the presence of minute proportions of certain volatile organic acids, which need not be specified. This smell is well marked when the urine is acid; but when it is alkaline from fixed alkali the urine acquires a sweetish odour instead, and when alkaline from decomposition becomes ammoniacal. Diabetic urine has a peculiar sweetish smell.

9. *Grape or starch sugar*. *Glucose*. *Dextrose*. ( $C_6H_{12}O_6, H_2O$ ).—A trace of this substance is frequently, if not always, present even in healthy urine. Occasionally it is found in excess under the influence of various morbid conditions of the system. Its habitual presence in quantity is the distinctive feature of the malady known as diabetes mellitus. Diabetic urine is usually of high specific gravity, has a sweet taste, very rapidly develops torulæ, ferments on the addition of yeast with the disengagement of carbonic acid gas, and (as one of the names of its saccharine constituent implies) rotates the plane of polarisation to the right.

a. *Qualitative tests for sugar*.—Many tests for the presence of sugar, some founded on the facts above enumerated, have been devised. One of the readiest, though not the most delicate, is that known as Moore's test. It consists in boiling a mixture of equal parts of the suspected urine and of liquor potassæ in a test-tube; when if sugar be present a deep reddish-brown colour, due to the decomposition of the sugar, becomes developed. The chief objections to this test are, that in concentrated urine, and in urine containing albumen or blood, a distinct deepening of colour also takes place, and that if the reagent contains lead, as it often does when kept in glass bottles, the deepening of colour becomes, in urine containing albumen, somewhat intense. Dr. George Johnson has called attention

to the fact that if, to the mixture of diabetic urine and liquor potassæ, made as for Moore's test, a few drops of a saturated aqueous solution of picric acid be added, boiling causes the fluid to acquire a characteristic purple or claret colour, which is more or less deep according to the amount of sugar present, and may be almost black. No change of colour, saving that due to the yellowness of the picric acid, takes place in urine free from sugar; but the minutest trace of grape-sugar evokes the characteristic reaction. The test is exceedingly delicate. Another accurate and trustworthy test is that known as *Trommer's* or *the copper test*, which depends on the power possessed by grape-sugar of decomposing the salts of copper and throwing down the insoluble red suboxide. It may be applied as follows:—

Mix the suspected urine with half its volume of solution of caustic potash or soda. If much precipitate be produced, it should be separated by filtration. Then add a few drops of a dilute solution of sulphate of copper, and heat the mixture in a test-tube. Even before the boiling-point is reached (if sugar be present) the characteristic precipitate will begin to appear; and as soon as this point has been attained the heat should be withdrawn, since other substances besides sugar effect by prolonged ebullition a reduction of cupric salts. The effect of this process on diabetic urine is that after a few seconds the mixture suddenly turns of an intense opaque-yellow colour and in a short time an abundant yellow or red sediment falls to the bottom. The test is best applied by using a ready-made alkaline solution of tartrate of copper.

*b. Quantitative tests for sugar.*—By means of a standard solution of the kind just referred to, Trommer's test may be made available for determining the quantity of sugar in urine. *Fehling's* solution, which is employed for the above purpose, is thus prepared:—Dissolve 34·64 grammes of pure crystallised sulphate of copper in 200 c.c. of distilled water. Separately dissolve 173 grms. of pure crystals of Rochelle salt in 480 c.c. of solution of caustic soda (sp. gr. 1·14). Mix the two solutions and dilute up to a litre. Ten c.c. of the mixture contain ·3464 gm. of cupric sulphate or ·108 gm. of cupric oxide, and represent ·05 gm. of pure anhydrous grape-sugar. This mixture has a great tendency to spoil by keeping. To obviate this it is advantageous to prepare the solutions as follows:—Dissolve 34·64 grms. of cupric sulphate in distilled water, dilute up to a litre, and keep in a separate bottle. Dissolve 173 grms. of Rochelle salt in 350 c.c. of distilled water, and heat to boiling; on cooling add 600 c.c. of solution of caustic soda (sp. gr. 1·12) that has been previously boiled, and make up to a litre with distilled water. The second solution is to be kept in a separate bottle, and to be mixed with the former in equal proportions when required for use.

To estimate the amount of sugar present in diabetic urine dilute 10 c.c. of urine with distilled water up to 200 c.c.; and pour into a Mohr's burette. This dilution is to reduce the sugar below 1 per cent. Then place 10 c.c. of Fehling's solution, or 20 c.c. of the mixture last considered, in a small flask, add distilled water up to 50 c.c., and boil the whole over a Bunsen's

flame—the flask resting on some wire gauze immediately below the Mohr's burette. Then allow the diluted urine to flow slowly into the boiling copper solution until the blue colour has nearly disappeared. After this point the urine must be added more cautiously, and the flask well agitated after each addition. The precipitated sub-oxide settles rapidly on removing the flame, thus allowing any tinge of blue in the supernatant fluid to be readily seen on holding the flask obliquely over a white ground. So long as any trace of colour remains more urine must be added, and the boiling must be continued. To make sure that all the copper has been precipitated a little of the test-mixture should be filtered and tested with ferrocyanide of potassium and acetic acid. The appearance of a brown coloration or precipitate indicates the presence of copper. When once the examination of the urine has been commenced it should be completed as soon as possible, to prevent any re-resolution of the sub-oxide. Supposing 60 c.c. of the diluted urine have been required by the 10 c.c. of Fehling's solution, then every 60 c.c. of the diluted urine, or every 3 c.c. of the urine itself (since it has been diluted twenty times), contains .05 gm. of sugar, or about 1.6 per cent.

Another method, known as *Knapp's*, may be employed. It possesses certain advantages over Fehling's process. The test solution is easier to make, it keeps a long time without alteration, the analysis requires a shorter time, and the termination of the reaction is more easily determined. The process is based on the power possessed by grape-sugar of reducing to the metallic state the mercury contained in a boiling alkaline solution of mercuric cyanide. 100 parts of sugar reduce 400 parts of cyanide. The standard solution is prepared by dissolving 10 grms. of the cyanide in 600 c.c. of distilled water, adding 100 c.c. of solution of caustic soda (sp. gr. 1.145) and diluting up to a litre with distilled water. 40 c.c. of the mercuric solution (containing .4 gm. of the cyanide, and equivalent to .1 gm. of sugar) are heated in a flask, and the diluted urine, as in Fehling's process, slowly added until the whole of the mercury is precipitated. The mercury falls rapidly, and the completion of the process can be ascertained by bringing a drop of the supernatant fluid into contact with a piece of wet filter-paper which has been exposed to the fumes of hydrochloric acid, and subsequently to sulphuretted hydrogen. A trace of dissolved mercury gives at once a yellow or brownish coloration.

Both of the above analyses should be repeated a second time in order to ensure accuracy.

The picric-acid test may also be made available for the quantitative determination of diabetic sugar.

10. *Amorphous phosphate of lime* ( $\text{Ca}_3, 2\text{PO}_4$ ).—This precipitates only in alkaline urine; it forms an amorphous sediment like that of the urates, but does not carry with it the urinary colouring matter. The application of heat increases the precipitate, and not unfrequently causes it. It is dissolved, however, on the addition of a drop or two of nitric acid. It often forms an iridescent pellicle on the surface.

11. *Crystallised phosphate* ( $\text{CaH}_2\text{PO}_4$ ).—Dr. Roberts regards this

sediment, which is rare, as an accompaniment of grave disorders. It occurs in rods and needles, which are often arranged in tufts and stars.

FIG. 77.—Phosphates  $\times 500$ .

12. *Ammoniaco-magnesian phosphate* ( $\text{H}_4\text{NMg}_2\text{PO}_4$ ) always falls in ammoniacal urine. Its crystals occasionally appear in slightly acid urine; but are much more frequently observed in that which is alkaline, and then often associated with the amorphous phosphate. They are occasionally met with as an habitual constituent of freshly voided urine. The ordinary crystalline form is that of a triangular prism with bevelled ends. But this is liable to numerous modifications.

13. *Oxalate of lime* ( $\text{CaC}_2\text{O}_4, 2\text{H}_2\text{O}$ ).—The presence of oxalic acid in urine is not surprising considering that it, with carbonic acid, is one of

FIG. 78.—Oxalate of lime  $\times 500$ .

those ultimate substances into which organic matters become reduced. Its presence is doubtless, in the majority of cases, due to such reduction, but sometimes it depends on the ingestion of articles of diet, such as rhubarb, which contain it. It occurs in the urine in combination with lime, usually forming small oblique octahedral crystals, and occasionally dumb-bell-shaped bodies. The crystals generally fall, entangled with the mucus, and when large may be seen as shining

points with the naked eye. Their occasional presence is a matter of little importance; but when they are of habitual occurrence there is reason to fear the formation of oxalate of lime calculi, and there is often some obvious impairment of health. Oxalate of lime rarely occurs in alkaline

or neutral urine. It is readily soluble in the mineral acids, and precipitable from solution by excess of ammonia.

14. *Carbonate of lime* ( $\text{CaCO}_3$ ) is sometimes deposited as an amorphous powder in alkaline urine, and is occasionally found in the form of minute rounded calculi, with a well-marked concentric structure.

15. *Albumen*.—This substance is seldom met with in healthy urine, and its presence, in any quantity at least, is one of the most significant indications of renal disease. It is observed under various circumstances. Whenever suppuration occurs in connection with any of the urinary organs, and pus is discharged into the urine, albumen is present in small proportion. In many specific fevers and other febrile disorders, in pregnancy and the puerperal state, albuminuria is liable to occur. In congestion of the kidneys, due to heart disease, bronchitis, or obstruction of the renal veins or arteries, again, albuminuria is frequently observed. The most important causes of this condition, however, are inflammation of the kidney, and those various chronic lesions which are usually comprehended in the term ‘chronic Bright’s disease.’

It is not uncommon to find temporary or occasional albuminuria in persons who presumably have no kidney disease, and are not suffering from any of the febrile or other disorders in which the occurrence of albuminuria is a recognised incident. In such cases the albuminuria may be regarded as functional. To some of these Dr. Pavy has applied the term cyclical. In cyclical albuminuria, which occurs mainly in young adults, albumen shows itself for the most part on rising from bed or from the recumbent position, and has been referred by Dr. Ralfe to the increased blood-pressure in the kidneys induced by the assumption of the erect posture. In other cases the attacks are intermittent or paroxysmal, and occur also for the most part during the periods of puberty and adolescence. In some of these, the albuminuria appears to be due to exposure to cold, and (as will be hereafter shown) not improbably has some relation to hæmoglobinuria; in some it appears to be induced by muscular exercise; in some it seems attributable to over-study and mental anxiety, and in some to the influence of certain articles of diet, especially raw eggs. The patients in whom functional albuminuria is observed are, for the most part, of delicate appearance; and the quantity of albumen present in their urine is generally very small.

The presence of albumen in the urine may always be recognised by its coagulation under the influence of heat or nitric acid. To apply the former test, a portion of the urine should be placed in a test-tube and then boiled by means of a spirit lamp. If it contain albumen, opaque flakes form in it, which render it turbid, and gradually fall to the bottom of the glass. If there be much albumen present, turbidity appears before the urine begins to boil; if there be only a trace, actual ebullition is essential to its production. In the employment of heat one or two precautions are necessary to be observed. In the first place, albumen is not precipitated if the urine be alkaline, and hence such urine should first be acidified by the addition of a few drops of acetic acid. In the second place, in slightly

alkaline or neutral urine, heat is apt to throw down a deposit of amorphous phosphates. These, however, dissolve on the addition of an acid. The nitric acid test may be applied either by dropping a few minims of strong nitric acid into a test-tube charged with the urine to be experimented upon, when, if albumen be present, a more or less abundant white precipitate will fall; or preferably as follows:—Charge a test-tube to a depth of  $\frac{1}{2}$  or  $\frac{3}{4}$  inch with strong nitric acid, and then pour a small quantity of urine slowly down the side of the inclined tube so that it may rest on the acid without mixing with it. If albumen be present an opaque white cloud, disc-like in form, immediately appears in the plane of contact of the two fluids. This latter method of employing nitric acid, which has been termed ‘the contact test,’ is probably the most delicate of all qualitative tests of the presence of albumen. The fallacies which may arise in connection with the nitric acid test are: first, that the urine of patients who are taking cubebs or copaiba is apt to become slightly turbid under the influence of nitric acid; second, that in concentrated urine, and such as is rich in urea, some deposition of urates or of nitrate of urea may occur; and third, that the addition of a very minute proportion of nitric acid does not always precipitate albumen, while the addition of an excessive quantity may prevent its precipitation altogether. A saturated aqueous solution of picric acid also precipitates albumen. In order that it may act well picric acid should be present in relative excess; it is advisable, therefore, in employing this test to mix equal bulks of urine and picric acid solution. Picric acid in excess does not re-dissolve precipitated albumen as nitric acid does; but in other respects the fallacies to be guarded against are the same for both tests. A practical advantage attaching to picric acid is that it may also be used in the form of powder. Dr. Johnson recommends that a quantity about equal to a pepper-corn should be added to an inch column of urine in a test-tube, and the mixture shaken until the powder is dissolved, when, if albumen be present, precipitation takes place. Sir W. Roberts has shown that a saturated aqueous solution of common salt, acidulated with about five per cent. of the dilute hydrochloric acid of the ‘British Pharmacopœia,’ renders albuminous urine opaque and milky; but that the opacity is not due to precipitation, and may be removed by dilution with water, or even with the urine which is being experimented upon. In this, as in the last case, equal bulks of urine and of reagent should be employed. This test may also be applied, like the nitric acid test, by gently pouring the urine on to a quantity of the saline solution in a test-tube, so as not to allow of their admixture, when, as in the other case, an opaque white disc appears in the plane of contact. The relative quantity of albumen present in any specimen of urine may be roughly but conveniently estimated by boiling the whole of the slightly acidified portion placed in a test-tube, and then allowing the coagulated flakes to subside. The apparent amount of albumen thus obtained, however, is far in excess of the actual amount present; which, even when the urine becomes solid by boiling, rarely if ever exceeds five per cent.

16. *Blood* may be found in the urine in various proportions and in different conditions, and may be furnished by any part of the urinary tract, from the kidneys downwards. The greater the quantity of blood passed, and the nearer its source to the external urethral orifice, the less will it deviate from the normal condition of blood, and the more readily will it be recognised. Its presence may be due to injury, congestion, inflammation, carcinomatous and other like growths, concretions, or parasites, involving either the substance or pelvis of the kidney, or some other part of the excretory apparatus, such as the ureter, bladder, or urethra. Hæmaturia occasionally also follows the use of cantharides or other drugs, and is frequently met with not only in those febrile disorders (small-pox, scarlet fever, and the like) which are attended with albuminuria, but in purpura, scurvy, and other affections of hemorrhagic tendency. When much blood is effused, it occasionally coagulates in the bladder; and may even coagulate in the chamber-pot. When present in smaller quantities and diffused uniformly throughout the urine, it imparts to it a slight degree of opacity or turbidity, and a tint resembling that of a dilute solution of the compound infusion of roses, or a peculiar smoky or dirty reddish-brown hue, varying in depth and distinctness according to the quantity of blood present. Sometimes the urine resembles porter. On standing it usually deposits a grumous, coffee-ground-like sediment. The presence of blood is additionally proved by the detection of albumen in the urine by the usual tests, and by submitting a specimen to microscopic examination, when almost always blood-corpuscles will be readily detected, sometimes disc-like, sometimes globular, sometimes crenate, occasionally retaining their colouring matter, but usually colourless, having imparted their pigment to the fluid in which they float. In a peculiar affection shortly to be described—paroxysmal hæmoglobinuria—although the urine contains abundance of blood colouring-matter, blood-corpuscles are never detected. And occasionally, also (as Dr. Mahomed has shown), in scarlet fever, prior to the occurrence of albuminuria and anasarca, there is a somewhat similar but slight escape of hæmoglobin alone into the urine, where it may be detected either by the spectroscope or by the guaiacum test. The latter may be applied as follows:—Place a drop or two of the urine in a small test-tube, add one drop of tincture of guaiacum and a few drops of ozonised ether; agitate, and then allow the ether to collect at the top. If blood-pigment be present, the ether acquires a blue colour, leaving the urine below colourless. No saliva must be mingled with the urine, and the patient must not be taking any salt of iodine.<sup>1</sup> Further, unless the tincture be freshly prepared the reaction is liable to fail.

17. *Bile*.—The colouring matter of the bile and the biliary acids are found in greater or less abundance in the urine in cases of jaundice. The former may, according to its amount, impart merely a yellowish tint, scarcely or not at all distinguishable from that of normal urine, or any variety of shade between this and a deep olive-green. Bile-stained urine

<sup>1</sup> Mahomed, 'Med.-Chir. Trans.,' vol. lvii.

seen by reflected light often looks almost black. The presence of biliary pigment in the urine may be readily detected by the addition of strong nitric acid, which produces, where the fluids first come into contact, an evanescent succession of green, blue, violet, and red tints. The test may be applied, either by placing a few drops of urine and a few drops of nitric acid close to one another on a white porcelain surface, and then allowing them to come together; or by putting a little nitric acid at the bottom of a test-tube, and pouring a small quantity of urine carefully on the top of it without allowing them to mix. In the former case the play of colours takes place at the line of mixture, in the latter in the horizontal plane of contact. Dr. G. Harley considers that the presence of the biliary acids in the urine is characteristic of jaundice from *retention* of bile. For their detection the following process (a modification of Pettenkofer's), may be employed:—Add a few drops of syrup to the urine, and then shake briskly in a test-tube until a froth has formed. Next allow a drop of strong sulphuric acid to flow down the side of the tube. As soon as the acid reaches the froth a beautiful purple colour develops rapidly. The reaction is facilitated by gently warming the side of the test-tube.

18. *Casts*.—In almost all cases in which albuminuria or hæmaturia is due to morbid conditions of the secreting structure of the kidneys, and occasionally in specimens of urine which seem to be free from both blood and albumen, microscopic cylinders which have been moulded in the urinary tubules, and are therefore termed casts, may be detected with the

FIG. 79.—Epithelial casts and cells from renal tubules  $\times 250$ .

aid of the microscope. Of these several varieties may be distinguished. The following enumeration comprises the more common of them.

*a. Epithelial casts* consist of renal epithelium. Occasionally the epithelium differs little from the normal epithelium of the tubules. More commonly the cells are granular and degenerating or

studded with oil-globules. In other cases the casts are formed mainly, if not entirely, of new-formed cells, which then assume an embryonic character, and have therefore more or less resemblance to pus-cells.

*b. Hyaline casts.* These present two well-marked varieties; of which one may be termed mucous, the other waxy. The former are exceedingly

aid of the microscope. Of these several varieties may be distinguished. The following enumeration comprises the more common of them.

*a. Epithelial casts* consist of renal epithelium. Occasionally the epithelium differs little from the normal epithelium of the tubules. More commonly the cells are granular and degenerating or

translucent and delicate, and consequently may readily escape detection. They are colourless, homogeneous, or ground-glass-like, with little or no refractive power, soft and flexible. They present soft but definite edges, are generally narrow and often of considerable length. They are proteinous, but not fibrinous; and are unaffected by acetic acid. The waxy casts also are transparent and homogeneous; but they are highly refractive, and therefore present well-marked shaded edges. Moreover, they are brittle, are apt to present transverse fractures, and

FIG. 80.—HYALINE CASTS  $\times 250$ .  
a a. Mucous. b b. Waxy.

vary largely in diameter and length. Like the former, they are not acted on by acetic acid; but they readily absorb biliary, blood, or other colouring matters. *c. Granular casts.* These vary in size, but are often of considerable bulk, and are studded more or less thickly and irregularly with granular matter, which often renders them perfectly opaque. They are hyaline, generally waxy, casts, which have either undergone granular

FIG. 81.—Granular casts  $\times 250$ .

FIG. 82.—Fatty casts  $\times 250$ .

degeneration, or are studded with degenerating cells, or enveloped in their debris. Indeed, compound granule cells are often seen distinctly embedded in them. *d. Fatty casts* are characterised by the presence of obvious fat-globules, which are sometimes of considerable size. Such

globules may be observed in either epithelial, hyaline, or granular casts. The fatty matter is not pure oleine, but seems generally to be a mixture of this with cholesterine and some albuminous matter. *e. Blood-casts.*

FIG. 83.—Casts containing blood  $\times 250$ .

Generally in renal hæmaturia the casts consist, in a greater or less degree, of coagulated fibrine entangling the corpuscular elements of the blood. The basis of the casts is here purely fibrinous; it is fibrillated, and dissolves in acetic acid. The blood-corpuscles may present pretty nearly their normal characters; they are generally, however, compressed and angular, and are often broken down and individually undistinguishable. The casts are necessarily more

or less deeply pigmented. Blood-corpuscles or blood-pigment may be present in epithelial or hyaline casts.

The various casts above described, and more especially perhaps the waxy and granular casts, occasionally contain crystals of either uric acid, oxalate of lime, or triple phosphate, or granules of urate of soda, or refractive globules looking like oil, but consisting of the crystalline bodies just named in combination with animal matter.

As regards the sources of urinary casts, it is important to bear in mind that the convoluted tubes of the kidneys which are functionally the most important can scarcely yield them, inasmuch as they are of comparatively large diameter, and are separated from the straight or collecting tubes by the narrow loops of Henle. Indeed, there is little doubt that casts found in the urine come exclusively from the loops of Henle and the straight tubes, that the descending limbs of the loops furnish the smallest, the ascending limbs those of intermediate size, and the straight tubes, and more especially their terminal portions, the largest casts.

On these and other grounds the significance of casts is less than is generally supposed. They are often absent in cases of albuminuria or chronic Bright's disease; and mucous casts are occasionally observed in jaundice, and in cases in which there is neither albuminuria nor kidney disease, and even in health. Epithelial casts usually imply acute affections; large hyaline, fatty, and granular casts, chronic and degenerative disease; while mucous casts have no special significance.

19. *Mucus and pus.*—In normal urine but little mucus is present; it falls as a scarcely perceptible cloud, and contains perhaps traces of vesical and urethral epithelium, and in the female squamous vaginal epithelium. When, however, there is any inflammatory condition of the mucous lining of the urinary channels or reservoirs, the mucous secretion becomes increased, cells are discharged in excess, and immature forms—in other words, cells identical with those of pus—are produced in greater or less abundance. The transition between mucus and pus is almost imperceptible. The dis-

charge, if sufficiently abundant, renders the urine turbid and slightly albuminous; and a sediment, which may present a greenish-yellow hue, presently forms. If the urine retains its acid reaction, this sediment is readily miscible with the urine; if, however, it becomes, as it is very apt to become, alkaline, then the sediment becomes tenacious and ropy. The secretion of inflammatory mucus has a remarkable influence in promoting the decomposition of urea; the urine, therefore, in these cases has a great tendency to become ammoniacal, to deposit earthy phosphates, and to acquire irritant properties. The abnormal secretions here described are most commonly furnished by the inflamed mucous membrane of the pelvis of the kidney, or bladder. But it must not be forgotten that pure pus may be poured into the urinary passages, either from renal abscesses or in consequence of the rupture of some neighbouring abscess into them, and that cells identical with pus-cells may escape from the renal tubules. Pus can be readily recognised by its microscopic characters.

20. *Flat*, excepting in connection with renal casts, is of rare occurrence in the urine. The presence of fluid fat in the form of globules is said to have occasionally been observed. Sir Dyce Duckworth records a case in which this was due to breaking down of sarcomatous growths in the kidneys. Crystals of cholesterine also have been met with. In a case of Dr. Murchison's, the cholesterine was traced to a pyonephritic cyst. The most interesting cases of fatty urine, however, are those in which this fluid presents a milky or chylous character, due to the presence of fatty matter in a molecular or amorphous condition. In these cases the urine contains albumen, fibrine, and leucocytes, in addition to fat; it hence tends to coagulate spontaneously; it coagulates with heat; a creamy layer rises to the top when it is allowed to stand; and it may be rendered clear, and the fat be separated, by agitating it with ether. Many of the globules which are commonly regarded as fat, and look like it, are really composed of some of the crystalline constituents of the urine in combination with animal matter, as may be shown by the effects of reagents and the appearance of a cross when they are examined with polarised light.

21. *Morbid growths*.—Tubercle, carcinoma, and other growths are apt to arise in various parts of the urinary organs; and it might hence be supposed that their characteristic elements should be occasionally discovered in the urine. It must be exceedingly rare, however, for such specific indications to be met with in connection with disease of the kidneys. In villous growths of the bladder, fragments may, no doubt, be detached and occasionally be discovered in the urine. It must be borne in mind, however, that the cells of the vesical epithelium have a great resemblance to typical cancer-cells, and may be easily mistaken for them.

22. *Spermatozoa* are sometimes present in the urine, and may be readily recognised in the sediment. Their presence is of little clinical importance, unless other symptoms combine to indicate the existence of abnormal spermatorrhœa.

23. *Animal and vegetable organisms*.—Hydatids are occasionally developed in the urinary organs, or hydatid cysts may open into them. The

urine under such circumstances may present actual hydatids or echinococci or fragments of one or the other. The peculiar laminated character of the hydatid membrane, and the hooklets of echinococci, are, under the microscope, quite unmistakable objects. In the endemic hæmaturia of Egypt, the Cape, Natal, and other parts of Africa, the symptoms are due to the presence, in the veins of the pelvis of the kidney, ureter, and bladder, of a small unisexual parasite, termed the *Bilharzia hæmatobia*. The presence of this affection may be recognised by the discovery in the urine of the ova and free embryos of the parasite (see later). The *filaria sanguinis hominis* is found in some cases of chyluria.

Sarcinæ have been observed in the urine when passed from the bladder. The bacillus of tubercle may be found in cases of tubercle affecting the genito-urinary organs. Lastly, bacteria and penicillium form rapidly in urine undergoing decomposition, and the yeast plant in that of diabetic patients.

### B. Concretions

These may occur in the form of a fine sand, in which case they are termed gravel, or in masses varying from the size of a tare or mustard seed upwards, when they are known as calculi; and may consist of any of the solid matters which have been described as occasionally separating from the urine, either separately or in combination. The most important of them are the uric acid, the uratic, the cystine, the xanthine, the oxalate of lime, the phosphatic, and the carbonatic.

Urinary concretions always contain more or less organic matter combined with their main ingredients, and in a large number of cases the nucleus has a different chemical constitution from the layers subsequently formed. Further, any foreign body, whencesoever derived, may form the nucleus around which urinary deposits accrete.

1. *Uric acid concretions* are the most common. They constitute five-sixths of the total number of renal calculi, and wholly or in part the great majority of those found in the bladder. Uric acid gravel consists of angular groups of crystals. Renal calculi of this material are small, round or oblate-spheroidal, often tuberculated bodies, which vary in colour from pale fawn to deep reddish-brown. In the bladder they attain a large size. They are hard, have a specific gravity of about 1·5, and are formed in concentric laminæ.

2. *Uratic calculi* are rare, and occur mostly in children under puberty. They are small, slate- or clay-coloured on the surface, smooth or granular, formed in thin, ill-marked laminæ, and very friable. They are readily soluble in boiling water.

3. *Cystine calculi* are very uncommon. When pure they are yellow, transparent, wax-like, and soft; the outer surface is somewhat crystalline, the sectional surface radiated. After long exposure to daylight they tend to assume a pale green colour. The circumstances which determine their formation are not known, but the tendency to them seems to run in families.

4. *Xanthine calculi* are also exceedingly rare, and have a close resemblance to those of uric acid.

5. *Oxalate of lime calculi* are next in frequency to those of uric acid. When in the kidney they are generally small, smooth, and of a dark colour. Here, however, but more particularly in the bladder, they often attain a large size, and are then usually tuberculated or spiny on the surface, constituting what are called mulberry calculi. These are laminated—the successive laminæ presenting a wavy or crenated character. Oxalate of lime calculi are exceedingly hard, and, though generally dark, vary much in colour. When very pure they are occasionally milk-white.

6. *Calculi of amorphous phosphate of lime*, or bone-earth, and those of *ammoniaco-magnesian phosphate*, are both exceedingly rare. The *fusible calculus*, which is composed of a mixture of these salts, on the other hand, is very common. This precipitate commonly takes place in ammoniacal urine, and hence is met with in the renal pelvis, or the bladder affected with chronic inflammation; and hence, further, it is specially apt to occur when calculi of other composition are producing irritation. Phosphatic matter, indeed, rarely forms the nucleus of a calculus; but it tends to accumulate on the surface of other calculi; and, when once it begins to collect there, is rarely succeeded by any other form of deposit. Phosphatic calculi are light, loose-textured, imperfectly laminated or amorphous, and white, grey, or dark yellow.

7. *Carbonate of lime* very seldom forms urinary calculi in the human being. It takes part, however, in the formation of the minute, dark-coloured, laminated concretions (sometimes called corpora amylacea) which are met with in the prostate. Sir W. Roberts quotes a case of Dr. Haldane's in which it was proved by post-mortem examination that carbonate of lime calculi, presenting similar characters, may be formed in the pelvis of the kidney and passed with the urine.

Calculi formed of blood, albumen, or fat have occasionally been met with, and Dr. Ord records the discovery of one consisting of nearly pure indigo.

### C. *The Specific Consequences of the Retention of Urea and other effete matters in the Blood.*

Structural disease of the kidneys, involving both organs generally, is attended with one important consequence: namely, the prevention, in a greater or less degree, of the elimination of urea, uric acid, and other products of the retrograde metamorphosis of nitrogenous matters, and their consequent retention in the blood and in the fluids which bathe the tissues. Following on this retention, and in part dependent on it, but in part, no doubt, dependent on the constant loss of albumen which commonly attends diseases of the kidneys, the blood undergoes deterioration; it grows watery, poor in albumen and corpuscles, and at the same time fibrine becomes relatively increased; the patient gets anæmic, and suffers from many of the usual consequences of anæmia. But, in addition to these phenomena, others of great gravity, and in the aggregate special to renal disease, sooner

or later supervene. These have been attributed simply to the retention of urea, but the experimental introduction of urea into the blood seems to show that this substance has little or no poisonous property; and the symptoms due to the complete obstruction of both ureters are altogether different from those of so-called 'uræmia.' It can scarcely be denied, however, that the phenomena in question are really referrible to the presence in the blood of some poisonous substance or substances which the kidneys fail to eliminate: if not urea, either some of the less oxidised matters which accompany it, such as uric acid, kreatine, kreatinine, and the like, or some alkaloidal poison, or leucomaïne, originating within the organism. The variety of the phenomena, indeed, would suggest the operation of several such poisons. Frerichs maintains, but on insufficient grounds, that some of them are due to the conversion of urea in the blood into carbonate of ammonia. The chief morbid phenomena here referred to are: thickening and contraction of the smaller blood-vessels; hypertrophy of the heart; anasarca and other dropsical effusions; local congestions and hemorrhages; inflammations of different organs, mainly those of the thorax; and, lastly, various functional diseases of the digestive and other organs, but, above all, of the central nervous system.

1. *Thickening and contraction of the smaller blood-vessels.*—Dr. G. Johnson showed some years since that in cases of chronic renal disease the walls of the minute arteries, both in the kidneys themselves and generally throughout the system, become extremely thick, and at the same time much contracted. He attributed the thickening to hypertrophy of the muscular coat, and the narrowing to the tonic contraction of this coat, and regarded the combined phenomena as an effort of nature to oppose the transmission of poisoned blood to the tissues. The thickening of the arterial tunics and the contraction of the arterial channels in chronic renal disease are now established facts. It has, however, since been maintained, more particularly by Sir W. Gull and Dr. Sutton, that the thickening is the result, not of muscular hypertrophy, but of a 'hyaline-fibroid' conversion; that it is, in fact, a change not unlike that which occurs in cirrhosis of the liver and sclerosis of other organs—a change which in a sense may be regarded as degenerative. In these latter views, so far as we have stated them, we are disposed to concur.

2. *Hypertrophy of the heart*, independent of valvular affection, has long been recognised as one of the most characteristic consequences of chronic kidney disease. The hypertrophy is general, and associated with more or less dilatation; but the changes are, perhaps, more obvious in the left ventricle than elsewhere. Dr. Quain has shown that the thickening of the walls is due in some degree to increase of the connective tissue, in other words to a kind of sclerosis; there is no doubt, however, that it is mainly dependent on muscular overgrowth, and that the stimulus to this overgrowth consists in some obstacle which the heart's action has to overcome. But since the valves and larger arteries are all, for the most part, healthy, this obstacle is not presented by them. There are obvious reasons why the veins must be considered to be inoperative in the

matter. We are compelled, therefore, to look to the small arteries and capillaries. And that the obstruction really does reside in these vessels is clearly shown by the high tension which by sphygmographic observation has been proved to prevail throughout the arterial system in such cases. It was formerly believed that the obstruction was caused by some abnormal attraction between the capillary blood-vessels or the tissues outside them and the morbid blood. It is, however, doubtless due to the contraction of the channels of the capillary arteries. Dr. Sibson has shown that generally in these cases the contractions of the two sides of the heart are not quite synchronous, and that there is a tendency, therefore, to reduplication of the heart's sounds.

3. *Anasarca and other dropsical effusions.*—Kidney disease is one of the most frequent causes of general anasarca. This condition often reveals itself first in regions in which the connective tissue is lax, as the scrotum, eyelids, and conjunctivæ, and is often recognised in the face before it appears in the lower extremities. There is generally neither lividity nor dilatation of veins; but the swollen surface presents an anæmic, wax-like character. Its cause is somewhat obscure. It is evidently not passive, for there is neither venous obstruction nor venous hyperæmia; nor, again, is there any obvious impediment to the healthy action of the lymphatic vessels. It must then be due either to some peculiar tendency in the serum of the blood to transude through the capillary vessels, or to the sweating of this fluid through the walls of the smaller arteries in consequence of the heightened pressure which the blood within them exerts. In reference to this question it should be mentioned that Dr. Mahomed has shown that in scarlet fever there is a stage, preceding the occurrence of anasarca, and even the appearance of blood or albumen in the urine, during which high arterial tension prevails, as demonstrated by the resistance of the pulse to pressure and by the form of the pulse-trace, and during which also the colouring matter of the blood may sometimes be recognised in the urine. The anasarca is not merely subcutaneous, but may involve the tissues of the larynx, the pulmonary texture, and other parts of the system; and is commonly associated with a dry skin and considerable diminution of urine; to which circumstances and to co-existent anæmia the presence of dropsy is no doubt attributable.

4. *Congestions and hemorrhages* are among the consequences of kidney disease. The most important of them are: effusion of blood into the substance of the brain, causing apoplectic symptoms; effusions into the choroid and retinal coats of the eye (*albuminuric retinitis*), attended with itching across the temples and at the occiput, and leading to atrophic changes and impairment of vision, or even absolute blindness; and extravasations into the lung-substance, producing the condition known as pulmonary apoplexy. The causes of these hemorrhages are, in part, the same that induce anasarca; but in chronic renal disease there is a marked tendency to atheromatous and fibroid degeneration of arteries, and hence effusions of blood are in some cases due to rupture of diseased and enfeebled vessels.

5. *Inflammatory affections* are of frequent occurrence. The most common and serious of these are inflammations of the pericardium and pleuræ, of the larynx, bronchial tubes, and lungs. But inflammation may also affect the abdominal viscera; and, indeed, no part is wholly exempt from liability to it. When anasarca is present it is of course common for an erythematous blush to make its appearance somewhere or other on the surface, and even for erysipelas or superficial gangrene to occur.

6. The *functional consequences* of renal disease are very numerous. Dyspepsia, nausea, vomiting, hiccough, and diarrhœa, the former three especially, are common phenomena, even when the stomach is healthy. Palpitation and dyspnœa, or hurried respiration in asthma-like paroxysms, are not unfrequently observed in cases in which the heart and lungs present little if any sign of disease. The Cheyne-Stokes respiration in its most typical form is probably more frequently observed in uræmia than in any other disease; usually when the patient is suffering from cerebral symptoms, but occasionally when he seems free from them; and continuing maybe without interruption for days or weeks together. Amblyopia, of temporary duration, deafness, drowsiness, headache, giddiness, irritability, subsultus, tremors, hypochondriasis, and even maniacal disturbance and wakefulness, are all of them liable to arise. But the most serious of the functional disturbances of the nervous system are epileptiform convulsions, apoplectic attacks, and coma. The convulsions are undistinguishable from those of true epilepsy, and often occur in groups. The apoplectic attacks are those formerly referred to serous apoplexy, and are typical apoplectic seizures. Coma, of course, attends both the epileptic and the apoplectic attacks. But not unfrequently the patient, apart from the occurrence of any fit, falls into a drowsy semi-comatose state, which may continue with little change for some weeks. It is in this condition that the Cheyne-Stokes respiration is chiefly observed. The last three kinds of cerebral affections are exceedingly dangerous, and in large proportion fatal.

D. *The non-specific Morbid Phenomena which attend on and characterise Lesions of the Kidneys*

Other symptoms which attend and indicate the presence of renal disease are totally independent of impairment or suppression of the proper functions of the kidneys. These are: symptoms which are determined by the locality of the diseased organ, and such as are referrible to it as a focus of inflammation or other morbid processes. Among the former may be comprised pain and tenderness, tumour, and the effects of pressure; amongst the latter the general symptoms of inflammatory fever when the organ is inflamed, the cachexia which attends the development of malignant disease, and the anæmia which results from the continued escape of blood, or of that important element of the blood—albumen.

## II. PYELITIS

*Causation.*—Inflammation of the lining membrane of the kidney may be excited in various ways. It seldom results from exposure to cold, or arises in connection with ordinary nephritis. It may, however, be induced by the use of certain medicinal irritants, such as cantharides and turpentine, which probably induce at the same time a similar condition in the lining membrane of the bladder, and in the secreting tissues of the kidneys. But its most frequent cause is direct irritation of the mucous surface, due either to the constant fretting of a renal calculus or to the influence of unhealthy discharges or decomposing urine, as occurs in cases of long-continued obstruction of the urinary passages. Independently of the last condition, vesical inflammation is apt to creep by continuity along the ureters to the pelves, and thence to the infundibula and calyces.

*Morbid anatomy.*—The anatomical signs of pyelitis are congestion, thickening and softening of the mucous membrane, sometimes associated with interstitial hemorrhage; and the discharge from its surface of mucus containing shed epithelial cells and pus-like corpuscles, and, it may be, blood. If the affection be persistent or intense, other phenomena probably supervene; the thickened mucous membrane may become opaque, yellow, or grey, and lose its vivid redness; suppuration may arise; false membranes may form; or ulceration may take place. Further, the effect of the unhealthy products of the mucous surface upon the urine is to render it ammoniacal and to promote the precipitation of earthy phosphates, which are then apt to concrete on the inflamed surface. Other changes which are liable to ensue in the course of pyelitis depend on impediment to the escape of urine from the inflamed cavity: they are dilatation of the pelvis, infundibula, and calyces, and atrophy of the secreting structure. Again, inflammation may extend by continuity from the pelvis to the renal substance, and abscesses may consequently form in it. Suppurative pyelitis, especially if it be confined to one kidney, and pus can escape freely from it by the natural passages, may continue for years with little or no additional mischief; and, even if complete obstruction of the ureter arise, it is possible that the whole thing may become quiescent, the expanded, atrophied, and indurated renal substance losing all its functional power, and the pus in the dilated calyces and the rest of the renal cavity drying up into a creamy, putty-like, or mortary substance. In other cases, however (and this may happen whether the ureter be wholly or only in part obstructed), the renal abscess takes another course. It behaves, in fact, as any other abscess originating in the vicinity might behave. It first transgresses its original renal limits, and then forms sinuses which enlarge and burrow in various directions. Thus, it may perforate the diaphragm, and open into the pleura or lung; or it may discharge in the loin; or it may rupture into the peritoneum, or open directly into the adjoining colon; or, descending along the psoas muscle, it may point under Poupart's ligament, or gravitate towards the lesser trochanter;

or lastly, passing into the pelvis, it may communicate there with the rectum, bladder, or vagina.

*Symptoms and progress.*—The specific symptoms of pyelitis comprise pain and tenderness in the loin, irritability of the bladder, and modification of the quality of the urine. The pain in the loin is apt to shoot into the abdomen, and especially downwards to the labium or testis of the corresponding side and along the inner aspect of the thigh. The tenderness reveals itself, and the pain is aggravated, during movement of the body; but especially if the affected side of the abdomen be firmly grasped, or the thigh be flexed by its own muscular efforts on the abdomen, in which case the enlarging bulk of the psoas muscle presses on the inflamed organ. There is probably irritability of the bladder, with pain and scalding in micturition. The water is more or less turbid from the presence of mucus, or it contains pus or blood, or both. It is usually acid; but, after a time, is apt to become ammoniacal from the decomposition of urea, and then to deposit amorphous and crystalline phosphates. It does not necessarily contain renal casts. Their presence indicates of course simultaneous involvement of the secreting structure of the kidney. Sometimes the discharge of pus is profuse; and both in this and in other cases the products of the inflamed surface are not unfrequently passed intermittently: temporary obstructions probably taking place in the ureter, in consequence of which they are retained and accumulate in the renal cavity with aggravation of local symptoms, and the urine becomes for the time comparatively clear and healthy. The general symptoms are mainly those of inflammatory fever. This assumes for the most part a remittent character, and is often attended with rigors. Vomiting and diarrhoea are not unfrequent.

The symptoms, progress, and results of pyelitis differ in different cases. If one kidney only be affected, the disease may continue indefinitely without any very serious impairment of the patient's health—indeed, the organ may become totally disorganised with little or no obvious detriment to health; but, on the other hand, the formation of an abscess is in any case attended with many risks, and its continuance may cause death by slow exhaustion, aggravated probably by the presence of hectic fever or lardaceous degeneration, or by the supervention of some intercurrent affection. When, however, both kidneys are involved, as may happen in calculous pyelitis, and as nearly always takes place when pyelitis is secondary to bladder disease, the symptoms which the patient presents are necessarily greatly aggravated, and the probability of an early fatal issue is much increased. For, in addition to the risks which attend disease confined to one kidney, we have now the additional risks which arise from the liability to retention of urea in the blood, and those which flow from the comparatively wide extent of the inflamed district. The patient passes into a typhoid condition, attended with muttering delirium, and not unfrequently complicated with epileptiform convulsions and coma.

Accumulation of pus in the kidney may be suspected when the discharge of pus with the urine ceases suddenly and continues in abeyance; it may also be suspected when, following upon symptoms indicative of

pyelitis, rigors take place, and at the same time throbbing pain and tenderness manifest themselves in the region of one of the kidneys. The diagnosis of an abscess must be based partly on the persistence of the above conditions, partly on the presence of increasing fulness in the neighbourhood referred to. If the abscess point externally all doubt will speedily be removed. Under other circumstances many difficulties will necessarily present themselves.

*Treatment.*—In the treatment of pyelitis it is of primary importance to ascertain its cause, and to remove or obviate it if possible. Thus, when it depends on retention of urine, from stricture, enlarged prostate, or paralysis of the bladder, our aim must be (if not to cure these lesions) at all events to empty the bladder periodically, and if necessary to wash it out with antiseptic solutions; when it depends on the presence of renal or vesical calculi we must endeavour to remove them, or, failing this, to maintain rest; if the inflammation be connected with gout, scrofula, or any other special cachexia, it will probably be well to modify our treatment accordingly.

When pyelitis is acute, and the local symptoms are severe, it may be necessary to remove blood from the loin either by cupping or by leeches, and to use hot fomentations, poultices, ice-bags, or equivalent applications. Counter-irritants, too, always excepting cantharides, may be employed. The administration of opium, in doses sufficiently large, and sufficiently often repeated to relieve pain and procure ease and rest, is of essential importance. Moderate purging, voluminous bland clysters, and hot baths are also valuable aids. When the disease assumes a more chronic character local measures become less important, and opiates also are comparatively little needed. It may, however, still be desirable to give the latter in small doses, or to administer some other form of sedative or anodyne, such as hyoscyamus, belladonna, or chloral hydrate. But tonics and nutritious diet now become our most valuable remedial agents; among the former, quinine and the other vegetable bitters and iron (particularly the perchloride) and cod-liver oil, must be especially enumerated. If the urine be alkaline, nitromuriatic acid or some other mineral acid may be beneficially combined with the other remedies. Buchu, pareira brava, and uva ursi, so much appreciated by surgeons in the treatment of chronic inflammation of the urinary bladder, are probably equally useful in the treatment of pyelitis. If the stomach be irritable, as it not unfrequently is, our treatment must be modified with the object of overcoming this irritability. When there is clear indication of the formation of an abscess in or around the kidney, an early and free opening should be made into it, for by that means not only may the extension of the abscess in other directions be prevented, but the cure of the disease will not improbably be effected.

## III. CIRCUMSCRIBED AND SUPPURATIVE NEPHRITIS

*Causation.*—The chief causes of the conditions about to be considered are : obstruction of the renal arteries or arterioles by thrombi or (in the case of cardiac disease or pyæmia) by emboli ; extension of inflammation from the pelvis of the kidney or other neighbouring parts ; and accidental injury.

*Morbid anatomy.*—The results of arterial thrombi or emboli are the same in the kidney as elsewhere. If the obstructed vessel be of large or medium size, the district to which it leads becomes deeply congested, blood accumulates and stagnates in the arteries, veins, and capillaries, and escapes from them, by rupture or otherwise, not only into the intertubular tissue, but into the Malpighian capsules and convoluted tubules. The affected district is at first of a deep red or reddish-black colour and well defined, resembling a patch of pulmonary apoplexy ; but gradually it becomes decolorised, and acquires an opaque, buff-coloured, cheesy aspect, when, if it be examined microscopically, the small vessels will be found loaded with pigment-granules and oil, and the epithelium of the tubules fatty and disintegrating. Sometimes it softens, sometimes suppurates. But the disintegrated tissues may also undergo absorption, and a patch of cicatricial tissue result. In the embolism of cardiac disease, and especially in that occurring in pyæmia, the infarctions are for the most part small and numerous, and speedily suppurate. In such cases, on removing the capsules, beads of pus, each surrounded by a congested halo, may be seen projecting from the surface of the organ ; and on making a vertical section small abscesses or groups of abscesses, similarly surrounded, may be observed extending in a radial direction from the periphery to the mucous surface. These may vary from mere points up to the size of a filbert or walnut. They originate in the intertubular spaces, but soon involve and destroy the tubules themselves and the other renal structures. When inflammation extends from the pelvis of the kidney there is often general congestion with enlargement of the organ ; but the special feature of such extension is the formation, in both medulla and cortex, of minute close-set abscesses grouped in comparatively large and well-defined but not very numerous clusters. Abscesses of the substance of the kidney are attended with various results. Sometimes their contents gradually concrete into a material like thick cream or moist plaster of Paris, consisting of disintegrated and fatty cells, molecular matter (partly earthy, partly oily), and cholesterine. In the most advanced examples of this kind of change the glandular substance of the kidney is hollowed out into a series of cavities, each one corresponding to a medullary cone and its associated cortical lobule, which are bounded externally, and separated from one another and from the pelvis, by thin fibrous laminæ or dissepiments. Sometimes the abscesses open and discharge their contents into the infundibula ; sometimes they extend beyond the limits of the kidney ; and then in either case the affection becomes indistinguishable, pathologically and clinically, from suppurative pyelitis.

*Symptoms.*—It would be almost impossible to lay down any definite rules for our guidance in reference to the diagnosis of the above affections. In a large number of cases the renal symptoms are necessarily masked by the graver morbid conditions with which they are associated. Thus when renal abscesses result from embolism, pyæmia, or inflammation commencing in the pelvis of the kidney, the febrile or typhoid symptoms referrible to the primary malady may perhaps become in some degree aggravated, the prospects of amelioration somewhat diminished, the fatal event hurried; but probably nothing points specially to implication of the substance of the kidney. Even if the urine be scanty or contain blood, albumen, casts, pus-cells, or leucocytes, there is nothing to show that such conditions may not be the result of some other variety of renal inflammation. If large abscesses form, the symptoms and consequences will be those of suppurative pyelitis.

The *treatment* of these cases (if they call for treatment) does not differ from that of pyelitis.

#### IV. ACUTE BRIGHT'S DISEASE

(*Acute Albuminous, Desquamative, or Tubal Nephritis*)

*Causation.*—This affection may be produced by many different causes. It may result from simple extension from the inflamed pelvis in pyelitis; it may be due to the influence of cantharides and other poisonous substances; and it frequently accompanies erysipelas, pneumonia, and such like grave inflammations, as also variola, measles, cholera, and other specific fevers. Its most important causes, however, are exposure to cold or wet, and the scarlatinal poison. It occurs also in pregnancy.

*Morbid anatomy.*—In acute Bright's disease the morbid process implicates in a greater or less degree all the renal textures, and for the most part is generally diffused and involves both kidneys equally. (a) The vessels (and more especially those of the medulla, the Malpighian tufts, and the stellate veins on the surface) become congested; and occasionally, undergoing rupture, discharge blood into the interstitial tissue, or into the Malpighian bodies and tubules. (b) Proliferation of the nuclei in the membrane which invests the Malpighian vessels, and of those belonging to the muscular walls of the arterioles, not unfrequently occurs. Lymphoid or embryonic cells sooner or later accumulate around the arteries and in the intertubular tissue. They are first seen as a rule along the larger branches; and then accumulate about the bases of the pyramids, whence they spread partly into the medulla, but mainly into the cortex along the interlobular vessels. The process may thus reach the surface of the kidney, and by lateral extension implicate the connective tissue between the Malpighian bodies and convoluted tubules. (c) The epithelium of the renal tubules, and more especially that of their convoluted portions, gets cloudy and swollen, and there is a tendency to multipli-

cation of the nuclei. Consequently the tubules become distended and varicose, their channels get reduced in size or obliterated, and their contents acquire unusual opacity. At a later period the cells tend to become fatty and to break down, to separate from one another and from the membrane beneath, and to be shed; and new cells of embryonic character make their appearance among them. Lastly, the channels of the urinary tubules become occupied in a greater or less degree by casts, which are either cellular, hyaline, or granular, or consist of blood in a more or less altered condition.

But the diseased kidneys do not always, or indeed generally, present all the phenomena above described; and especially it is an important fact that in some cases the changes, even from the beginning, are mainly epithelial, while in others the interstitial tissue is from first to last the chief seat of disease. There is a tendency, however, in all cases, especially if they are prolonged, for the morbid processes to become generalised. Partly for convenience of description, partly because they represent tolerably well-defined types, we shall describe three varieties of the disease.

1. Catarrhal inflammation is the name which may be given to the slight and for the most part evanescent affection which is often met with in poisoning by cantharides and other such substances, in connection with certain inflammatory or infectious disorders, and under many other circumstances. In the first group of cases the tubal affection is associated with congestion or inflammation of the mucous membrane of the pelvis, and is for the most part limited to the medulla. In other cases, and indeed in most, the cortical tubes are mainly if not exclusively implicated. The naked-eye appearances are not very striking: there is enlargement and softening of the organ; its capsule can be readily peeled off; the stellate veins on the surface, the Malpighian bodies, and the medulla are all more or less congested; while the cortex (if the cortex be the main seat of disease) is probably somewhat paler or more yellow and opaque than natural.

2. Another variety is that which arises mainly from exposure to cold and wet, and is observed in ordinary cases of acute *idiopathic nephritis*. In this the predominating features are (as in the last case) congestion, and cloudy swelling of the epithelium. But the congestion is much more intense and general, and is not unfrequently associated with hemorrhage, either into the interstitial tissue, or, as is more common, into the renal tubules and Malpighian capsules; and the cloudy swelling involves the contents of all or nearly all the convoluted tubes, and probably in a greater or less degree the epithelium of the loops of Henle. The kidney, consequently, is much enlarged—sometimes indeed to twice its natural bulk—and softened; and its capsule admits of easy removal. The cortex is especially thickened. The aspect of the organ varies: in some cases the congestion is so extreme and general that the whole of the secreting structure, cortex and medulla alike, presents a deep red or claret colour; but more frequently the medulla is deeply congested, while the cortex, though studded with red points and streaks, is remarkable for its opacity

and pallor, resembling in this respect a hepatised lung. If the disease persist, interstitial changes, which may at first have been indistinct or absent, are apt to supervene.

3. Scarlatinal nephritis differs in many important respects from the last. The first observable changes are in the glomeruli, small arteries, and convoluted tubes. The internal elastic lamina of the arterioles, but mainly of the afferent branches, and the walls of the Malpighian capillaries, undergo hyaline thickening, which is attended with more or less complete obstruction of their channels; the nuclei connected with the Malpighian tufts (probably the epithelial nuclei) proliferate; the muscular nuclei of the smaller arteries likewise multiply; and at the same time cloudy swelling takes place in the epithelium of some of the convoluted tubes. Somewhat later, at the end probably of a week or ten days, other phenomena ensue. Lymphoid cells appear in the interstitial tissue, and occasionally in such excess that the diseased textures present the characters of adenoid tissue; and the epithelium of the convoluted tubes becomes more generally and distinctly swollen and cloudy. The scarlatinal kidney presents much the same appearance as that last described, but on the whole generally is smaller and less congested.

The results of acute Bright's disease are various. Sometimes at the end of a few days, a few weeks, or a few months, the morbid processes come to an end, and the kidneys revert to their healthy condition, or to a condition which is practically healthy but in which a few Malpighian bodies and tubes remain permanently atrophic. In other cases the disease becomes chronic, the convoluted tubes remain obstructed by their accumulated and degenerating contents, or the interstitial nuclear growth changes into fibroid tissue, and some one or other of the conditions presently to be described ensues.

*Symptoms and progress.*—The symptoms of acute Bright's disease vary much in severity, and are sometimes so trivial as to escape notice. Especially is this the case in many febrile and inflammatory disorders, where perhaps the only evidence of renal implication is the temporary presence of albumen and hyaline casts in the urine. The symptoms observed in severer cases consist mainly in fever, aching across the loins, an abnormal state of urine, and anasarca. The febrile phenomena comprise elevation of temperature, sense of chilliness and occasionally rigors, quickness, fullness, and hardness of pulse, heat and dryness of skin, flushing of face, clamminess of mouth with coating of tongue, thirst, loss of appetite, nausea and not unfrequently vomiting, headache and pains in the limbs. From the commencement, probably, the patient notices that his water is scanty. A few ounces only may be excreted in the course of the day and night; or there may be complete suppression for many hours. What is passed is abnormally dark and often turbid or grumous; its specific gravity is usually high; it contains abundant albumen, often blood, and a diminished quantity of urea; and, microscopically, it presents epithelial, hyaline, granular, or bloody casts. It often also contains amorphous urates and uric acid crystals. But notwithstanding the scantiness of the urine there

is generally a constant desire to pass water, and a sense of heat or pain in the bladder and urethra. Anasarca comes on early. It usually manifests itself first in the face, particularly in the eyelids and conjunctivæ, in the genital organs or about the ankles. But it soon becomes general, and may become enormous, especially in the specified regions, and in the most dependent parts. The skin at the same time tends to assume a peculiar pale waxy aspect. Dropsy is not limited to the surface, but takes place also into the serous cavities and into the tissues of different internal organs, causing, according to its seat, difficulty of breathing or other more or less serious consequences. Besides pain in the loins there may be actual tenderness there; and the pain may extend into the thighs, as in pyelitis.

The symptoms, however, are by no means always in accordance with the above sketch. Sometimes anasarca is the first intimation that the patient or his doctor has that the kidneys are affected, and it is only on further inquiry that the urine is found to be abnormal. Sometimes growing anæmia and weakness alone point to the kidney affection, which the examination of the urine then detects. Sometimes almost the first indication of disease is the presence of palpitation, orthopnoea, and lividity of surface, without any discoverable lesion of either the heart or the lungs. In some cases the urine is scanty, albuminous, and bloody, and yet no anasarca, and scarcely any other indications of impaired health manifest themselves. And occasionally also, while all other signs of renal inflammation are present, the urine remains free from albumen.

The progress and results of acute nephritis are very various. In a large proportion of cases recovery takes place, sometimes in a week or two, more frequently at the end of six or eight weeks, occasionally after the lapse of six or twelve months or more. The symptoms of returning health are chiefly restoration of the functions of the skin, subsidence of anasarca, and return of the urine to its normal quantity and character. At the beginning of convalescence, indeed, the urine is often in excess. The anasarca usually subsides before the urine gets quite free from albumen. It is not uncommon, however, especially after scarlet fever, for anasarca to persist even after the urine has become healthy. In a smaller proportion of cases, but unfortunately in far too many, the affection either ends fatally while it is still acute, or assumes a chronic and incurable character. The fatal event may occur at different periods, and may depend on one or other of the following causes: namely, oedema of vital organs, as of the larynx, or lungs, producing dyspnoea, lividity, palpitation, asphyxia; inflammation of the pericardium, pleuræ, lungs, or peritoneum; anæmia and debility; or, lastly, cerebral complications, especially coma and convulsions.

*Treatment.*—In the treatment of acute nephritis it is important to assuage if possible the inflammation which is in progress. For this purpose we may apply counter-irritants, hot fomentations, or cupping-glasses to the loins, or abstract blood by leeches or cupping from the same part. The patient should be kept warm in bed and clothed in flannel; warm or hot baths, or the wet pack, should be occasionally administered for the purpose

of promoting the action of the skin; and the bowels should be kept moderately free by saline purgatives. The measures just enumerated undoubtedly conduce to restore the functions of the kidneys, and it is on them we must rely if suppression of urine supervene. But, as is strongly urged by Dr. Dickinson, it is important also to remove from these organs the solid cylinders which are blocking up the tubules, and by their pressure obstructing the efferent veins. To this end the secretion of urine should, if possible, be promoted directly. It is uncertain how far diuretics are capable of effecting this purpose; but, at all events, it seems judicious to encourage the patient to drink water and other simple fluids, and to administer diuretic doses of the acetate or citrate of potash, nitrous ether, or other equivalent medicines. Digitalis is especially valuable. At a somewhat later period, when, in addition to other symptoms, anæmia is present, vegetable tonics and the preparations of iron are often of great value. The perchloride of iron, which is a diuretic as well as tonic, is a favourite remedy. The patient's diet should be nutritious, but light, easily digestible, and consist mainly of milk and farinaceous substances. Alcohol in any form is rarely needed, and generally likely to be injurious. If uræmic symptoms supervene active purgation by means of elaterium, compound jalap powder, or some other form of drastic purgative, or even the abstraction of blood locally or from the arm, should be employed. Other complications must be dealt with on general principles. There is a great tendency for nephritis to recur, and great care therefore should be taken during convalescence. Iron and vegetable bitters, change of scene, and residence in a warm climate are often at this time of great service.

## V. CHRONIC BRIGHT'S DISEASE

### A. *Chronic Parenchymatous or Tubal Nephritis (Large White Kidney and Fatty Kidney)*

*Causation.*—The causes of the sub-acute or chronic form of tubal nephritis, which we are now about to consider, are somewhat obscure. In a considerable number of cases the disease comes on, so far as we can see, spontaneously, or at any rate insidiously. But in some it is directly referrible to exposure to cold and wet; and in most cases probably is a sequela of the acute inflammatory affections last described. It is a disease mainly of early life, seldom occurring under three or over forty.

*Morbid anatomy.*—Anatomically the large white kidney is closely related to, if it be not identical with, those forms of acute Bright's disease in which the pathological changes involve mainly the contents of the tubules. In this case, as in those, the epithelium is swollen, cloudy, or faintly granular from the precipitation of proteinous particles, distends the tubes in which it is contained, renders them more opaque than natural, and contracts or obliterates their channels; in this, as in those, the axes of the tubes become blocked up in a greater or less degree by mucous, colloid, or

granular casts, while changes in the interstitial tissue are either absent or comparatively slight, or come on late. But congestion, which is an important condition in the acute disorder, is absent here. The phenomena above described belong mainly to the convoluted tubes, are sometimes limited to them, and indeed may involve a certain proportion of them only. Not unfrequently, however, they also implicate the loops of Henle, and may even extend into the straight tubes. The Malpighian bodies usually remain healthy; there may, however, be some multiplication of the nuclei of the capillaries of the glomeruli, and some degeneration of the epithelium investing them. The kidney thus affected is much larger than natural, sometimes twice its normal size, soft, and smooth on the surface; and its capsule can be readily removed. Its enlargement is due to the increased bulk of the cortex, which is white or yellowish, opaque, and sometimes ivory-like. It may be absolutely devoid of blood, or may present only a few vascular points and streaks. The medulla for the most part remains healthy. Both kidneys suffer.

With the continuance of the disease changes of more or less importance ensue. The swollen epithelium becomes fatty, and tends to break down, and when the change is advanced the tubules appear stuffed and opaque with fatty detritus. The fatty change may be general, in which case the cortical substance acquires a more or less uniform buff colour; or it may be irregularly distributed or more advanced in patches, when the organ looks as if it were sprinkled with bran. At this stage the Malpighian tufts are often studded with groups of fatty granules, or there is an accumulation of fatty detritus in the intervals between the tufts and capsules; and occasionally also fatty granules, in more or less abundance, occupy the interstitial tissue. The 'branny kidney,' as it is sometimes called, is often smaller than the typical 'large white kidney,' and may present an indistinctly granular surface. In connection with this fatty change we sometimes find distinct increase of the interstitial connective tissue of the organ. The kidney then tends to become small, and granular on the surface, and to present some of the characters of the contracted granular kidney which will presently be described. Fatty degeneration of the renal epithelium occurs in poisoning by phosphorus. It is sometimes also met with in diabetes and certain other disorders.

*Symptoms and progress.*—The early symptoms of the disease under consideration vary according to the circumstances under which it is developed. If it be a consequence of scarlet fever, or of any other variety of acute Bright's disease, the ordinary phenomena of acute nephritis precede them, and either at once, or after a series of remissions and exacerbations, merge into them. A common history is that the patient after some acute attack gets apparently well, but does not wholly lose his albuminuria; and that he continues fairly well, but with persistent albuminuria, or intermittent attacks of it, until at the end perhaps of some years characteristic symptoms come on. If it be of acute origin, lumbar pain, febrile phenomena, and smoky urine are amongst its primary symptoms. But whenever the disease comes on as a late sequela of some acute

form of nephritis, or independently of present inflammation, its symptoms creep on gradually. They are mainly scanty excretion of urine, rapid occurrence of general dropsy, and speedy manifestation of anæmia. In the early stage of the disease the urine is always diminished in quantity; not unfrequently three or four ounces only are passed in the twenty-four hours; and occasionally there is temporary suppression. Yet there is generally a good deal of irritability of bladder, and frequent desire to micturate. The urine, besides being scanty, is dark-coloured, of high specific gravity, and deposits a sediment. It contains a large quantity of albumen, and, under the microscope, presents more or less abundant casts, which are for the most part mucous or colloid, and if fatty changes have occurred granular, or studded with oily matter, or invested in fatty débris. Sometimes the casts are few in number or altogether absent. Uric acid crystals are often present, and sometimes very numerous and large. Urea is much diminished. Dropsy always comes on early, and soon becomes general and abundant, and, although liable to vary somewhat in degree, is, on the whole, very persistent. With the increase of dropsy the surface grows more and more pale and waxy-looking. The gradual supervention of anæmia is generally a striking feature of the disease. This is in part apparent only, and due to the presence of anasarca; but it is referrible mainly to actual deterioration of the blood, determined in some degree by the daily abundant loss of albumen. As in ordinary anæmia, persons with delicate skin not unfrequently display a fallacious appearance of bloom in the cheeks. Together with the above symptoms patients suffer from debility, restlessness, dyspnœa, loss of appetite, vomiting, and other symptoms of gastro-intestinal disturbance. Among the sequelæ or complications of the disease the following may be enumerated:—dropsical effusion into the pleuræ, lungs, or glottis; inflammation of the lungs, pleuræ, pericardium, or peritoneum; erythematous, erysipelatous, or gangrenous inflammation of the dropsical skin, more especially of the lower extremities and external genital organs; and hypertrophy of the heart. Lastly, uræmic symptoms are not unfrequent, especially headache and sickness, followed by convulsions or coma. It is important, however, to recollect that cardiac enlargement and albuminuric retinitis are less frequent, and as a general rule less pronounced, in this disease than they are in cases of contracted granular kidney.

Patients may of course recover from this disease, and the milder the attack the more likely is recovery to ensue. Favourable symptoms are: increase in the amount and diminution in the specific gravity of the urine, disappearance of albumen, restoration of the functions of the skin, and subsidence of dropsy. Casts may continue in the urine after albuminuria has ceased. If a cure take place it is generally within six months. Recovery is in many cases fallacious; the patient improves to a certain point only (it may happen indeed that both albuminuria and dropsy disappear), and then after remaining pretty well for a time he has a relapse of which he dies; or the disease is prolonged by alternate remissions and relapses for several years. Death usually occurs in from three to twelve

months, generally within six, either from extreme asthenia or from one of the complications which have been enumerated. But if we reckon the duration of the disease from the scarlatinal or other acute affection to which it may have been remotely due, it must be measured by years, and may certainly be as much as ten or fifteen.

B. *Chronic Interstitial Nephritis (Contracted Granular Kidney. Gouty Kidney)*

*Causation.*—Chronic interstitial nephritis is more common in men than in women, and is met with almost exclusively in advanced life. It rarely occurs under forty years of age, but is sometimes observed even in young children. The causes which determine it are not well understood. There is reason to believe that the tendency to it is sometimes hereditary. It is certain, too, that it is often combined with widespread changes of a similar kind in other organs. It is frequently associated with gout, and there is some obscure but undoubted connection between it and chronic lead-poisoning. Alcohol has certainly not the same tendency to produce this state of kidney that it has to cause cirrhosis of the liver. Nevertheless, there is good reason to believe that some cases may be referred to abuse of drink. Again, it must, we think, be admitted that the various inflammatory affections of the kidney already described, especially that originating in scarlet fever, and parenchymatous nephritis, tend in the course of years to produce a contracted granular condition of the organ, scarcely if at all distinguishable from that due to primary interstitial nephritis.

*Morbid anatomy.*—The *contracted granular kidney* is in distinct anatomical relation with the scarlatinal kidney, inasmuch as in both of them the morbid process commences in and implicates essentially the renal vessels and interstitial texture—the affection of the tubules and of their contents being secondary. Nevertheless, it cannot be pretended that they usually stand to one another in the relation of cause and effect. The typical contracted granular kidney is much smaller than the healthy organ, and occasionally not more than an ounce or half an ounce in weight. Its capsule is adherent, and on removal apt to carry with it small portions of the cortical substance. The surface is nodulated like that of a cirrhotic liver (the nodules being perhaps as large as hemp-seeds) and of a deep reddish hue. On section the cortex is found to be much reduced in thickness, the medulla atrophied, though in a less degree, and the texture of the organ generally dark-coloured and dense. Cysts of various sizes, and in more or less abundance, are often observed studding the secreting structure, but more especially the cortical portion. On microscopic examination, the Malpighian bodies are seen to be largely changed, they are much reduced in size, their capsules are thickened and laminated, and their capillary tufts are welded into almost homogeneous lumps; the convoluted tubes are atrophied, sometimes denuded of epithelium or lined with embryonic cells, sometimes stuffed with fatty contents, sometimes filled with hyaline casts, sometimes reduced to fibrous filaments or bands scarcely distinguishable from the surrounding tissues, sometimes con-

verted into microscopic cysts lined or not with distinct epithelium; the loops of Henle and the straight tubes show less important changes, nevertheless their epithelium may present fatty degeneration, they may be blocked up with hyaline casts, and occasionally some of them are converted into strings of cysts; the vessels, more especially the arteries, are much thickened, and at the same time reduced in calibre, while the larger ones are probably also atheromatous; and finally, the connective tissue of the organ is more or less extensively hypertrophied. This fibroid growth occurs mainly along the interlobular vessels, extending vertically from the surface to the junction of the cortex and medulla, and then spreads horizontally so as to involve in the first place, and most importantly, the immediately contiguous Malpighian bodies and convoluted tubes, leaving the straight tubes which occupy the centres of the lobules comparatively free. This distribution explains both the special atrophy of the Malpighian bodies and convoluted tubes, and the granular condition of the surface of the organ—the depressions corresponding to the intervals between lobules, the elevations to the comparatively healthy central portions which contain the straight tubes. In the early stage of the disease, as in the early stage of cirrhosis of the liver, the kidney is little if at all diminished in size, the granulations on the surface are absent or only slightly developed, and a new growth of embryonic tissue may be observed in all those regions which subsequently undergo contraction and atrophy. The changes above described occasionally affect limited parts of otherwise healthy kidneys; and often manifest themselves ultimately in the attenuated and compressed kidney-structure seen in advanced hydro-nephrosis. Further, as has already been pointed out, the fatty and granular conditions are not unfrequently associated. In which case the kidney is larger and more irregular in form than the simple granular kidney; its superficial granules are larger and paler; and its cortex is mottled with whitish and yellowish patches, due to *areæ* of fatty degeneration.

*The cystic kidney.*—There is probably no essential distinction between the cystic kidney and that just described, notwithstanding that the former may attain the bulk of a bullock's kidney, and the latter is usually unnaturally small. It has been mentioned that in the granular kidney obvious cysts are of common occurrence. There is no limit, indeed, to their size and number; the cause which produces them at one or two points in one case may be in general operation in another case, and hence in place of half a dozen we may have hundreds or thousands; and instead of being no larger than a pea or marble many of them may attain the size of a pigeon's egg or a still greater bulk. In some of the more remarkable cases of this kind the kidney during life constitutes an easily recognisable tumour, and post mortem may have the aspect of a multi-locular ovarian growth (consisting of little else than a congeries of cysts) probably measuring seven or eight inches in length, and weighing between two and three pounds. The contents of the cysts vary in character even in the same case. They are sometimes limpid, sometimes thick and treacly, sometimes solid and jelly-like. They may be colourless or straw-

coloured, or may present any tint between this and a dark brown or red. They may be clear, turbid, or opaque. They usually contain albumen and the ordinary salts of the serum of the blood, but rarely if ever any special urinary constituents. The more viscid accumulations probably contain colloid matter. Among microscopic constituents are observed in different cases granular or fatty matter, disintegrating cells, decomposing blood, and cholesterine. Further, the cysts are often lined with pavement-epithelium. There is reason to believe that they originate both in Malpighian bodies and in portions of renal tubules which, owing to inflammatory or degenerative changes, have been cut off from their connection with the rest of the secreting structure of the kidney. The abundant microscopic cysts observed in many cases of granular kidney certainly originate in convoluted tubules which, losing their epithelium or undergoing degeneration, become obliterated at points, distended in the intervals, and thus acquire a moniliform character. Another view, originally proposed by Sir John Simon, is that they arise in extravasated and overgrowing or dropsical renal epithelial cells.

It is a curious fact that in some of the most typical cases of cystic kidney similar cysts have been abundantly present in the liver.

*Symptoms and progress.*—The symptoms of granular kidney usually come on insidiously, and do not attract notice until the disease has made considerable progress. Indeed, it is often the occurrence of some complication that first calls attention to the presence of renal mischief. The patient, who had formerly enjoyed good health, gets thin, weak, and anæmic without obvious cause; he suffers from dyspepsia, has loss of appetite, nausea, and perhaps actual sickness; he complains of shortness of breath and palpitation; he is liable to bronchitic attacks; his eyesight becomes impaired; and he probably notices that he makes more water than he was accustomed to make, and that he has to get up several times in the night to pass it. At length he seeks medical advice, and the urine is found to be of persistently low specific gravity, and probably to contain albumen. In other cases attention is first seriously directed to the patient's condition by puffiness of the conjunctivæ or eyelids, or swelling of the legs or scrotum. In other cases, again, the first clear intimation of disease is the supervention of severe sickness or diarrhœa, or paroxysms of extreme dyspnœa, or œdema of the larynx, or the development of tremors not unlike those of paralysis agitans, or attacks of sudden blindness without visible optic changes and tending to remit, headache, giddiness, or uræmic convulsions, or an apoplectic seizure. The early symptoms, indeed, which are also in many respects those of the established disease, are multiform; and they are frequently masked by the presence of associated visceral lesions, more especially of the heart, lungs, liver, intestinal canal, or brain. Nevertheless there are certain phenomena which are specially characteristic of the disease and indicate its presence, and to these we will now direct attention.

The *urine* is almost always abundant, pale, limpid, and acid. Three or four pints, or even eight or ten, may be passed habitually during the

twenty-four hours. Its specific gravity is low, varying from about 1003 or 1004 to 1010 or 1012, and it contains but little urea or other normal urinary constituents. Nevertheless the total amount of urea discharged daily is often fully up to the normal standard. Albumen, though generally present, is in small proportion. It is sometimes, however, in excess; sometimes wholly absent. Microscopic casts, too, are scanty, and may be readily overlooked; they are for the most part hyaline and granular. The condition of the urine may, however, vary: sometimes because the renal disease is not one of pure interstitial nephritis, sometimes as a consequence of temporary congestion or inflammation; and late in the disease it is apt to become scanty, of comparatively high specific gravity, and at the same time highly albuminous, maybe bloody, and deficient in urea. Owing to the abundant and long-continued diuresis, and the scantiness or absence of albumen, cases of contracted granular kidney are occasionally mistaken for cases of diabetes insipidus. *Dropsy*, so common in other forms of Bright's disease, is often absent in this; and, even when present, is for the most part slight and variable and of late occurrence. It is sometimes limited to the conjunctivæ. But occasionally it becomes extreme, especially in those cases where also the urine becomes scanty, and hence mainly towards the close of life. It is in association with the contracted granular kidney that *thickening of the walls of the small arteries* and *hypertrophy of the heart* mainly occur. The degree of these changes is generally proportioned to the length of time during which the renal disease has been in progress, and to the degree to which the kidneys have shrunk. The hypertrophic condition of the heart is generally revealed by its heaving pulsation and increased area of dulness; and the general arterial affection by heightened tension of the larger arteries and incompressibility and prolonged tidal wave of the pulse. At a late period, however, the heart becomes weak.

In association with the continuance of the conditions here discussed, the patient becomes more and more enfeebled and incapable of exercise, and probably emaciates; he complains of dryness of mouth or thirst, loss of appetite, flatulence and nausea, and especially at a late period of constant and distressing sickness; his bowels probably are variable; he has attacks of difficulty of breathing coming on mainly at night-time, and presenting a good deal of resemblance to those of ordinary asthma; he suffers also from headache, giddiness, or sense of oppression or weight, is often disposed to somnolence, and becomes apathetic. His skin is harsh and unperspiring, and his complexion probably pallid; but he rarely becomes distinctly anæmic, or suffers from lumbar pain.

Many complications are apt to arise in the course of the disease, especially towards its fatal close. Inflammatory affections are common, more particularly inflammation of the pericardium and pleuræ, œdema of the glottis, bronchitis, and pneumonia. Functional nervous disorders also are extremely common, and among the most characteristic of them. They comprise (besides headache, somnolence, tremors, sickness, and delirium) epileptiform attacks or coma, which are frequently preceded by these or

other nervous phenomena, and attacks of amaurosis without obvious affection of the eyes, which are apt to come and go, but after a time to end in absolute blindness. Affections referrible to the circulatory organs, again, are of frequent occurrence; epistaxis and bleeding from the stomach and bowels and other mucous membranes are often observed; retinal hemorrhage or albuminuric retinitis is far more common in this than in any other form of kidney disease, and is not unfrequently one of the earliest indications of its presence; in addition to the characteristic thickening of the smaller arteries, atheromatous and calcareous changes in the arterial system are commonly present, and partly from this cause, partly from excessive blood-pressure within the vessels, hemorrhagic effusion into the substance of the brain is very liable to occur; again, thrombi are apt to form in the pulmonary arteries, leading to pulmonary apoplexy, and also in the systemic vessels and cavities of the heart. Lastly, it may be observed that granular degeneration of the kidneys is occasionally associated with similar disease in the liver and other organs, and that dysenteric ulceration not unfrequently supervenes.

Chronic interstitial nephritis is essentially a disease of long duration. It may certainly continue for ten years or more. The causes of death have been sufficiently indicated in the last paragraph; but the most frequent cause is uræmic poisoning, attended sometimes with convulsions, more frequently with coma.

### *C. Treatment of Chronic Bright's Disease*

The treatment of chronic parenchymatous nephritis is essentially the same as that of the acute disorder. Abstraction of blood, however, is less likely to be required. Perspiration should be promoted by the measures previously discussed or by the Turkish bath. The bowels should be kept freely open by saline purgatives. Diuresis should be solicited by bland drinks, alkalies, and digitalis. Moreover, the stimulant diuretics, broom, juniper, and squill, which are unsuitable in the acute disease, may be given with advantage here. The rapid development of anæmia points significantly to the use of iron, and there is no doubt that ferruginous preparations, and especially the perchloride of iron, are more valuable in this than in any other form of nephritis.

In dealing with cases of granular disease the incurability of the lesion must not be forgotten. If no special symptoms are present it may be desirable to promote the action of the skin by the wearing of flannel and the use of baths, to keep the bowels open by occasional mild purgatives, to give tone to the system by the employment of iron in combination with vegetable bitters, and to support strength by wholesome, nourishing diet, not superabundant in quantity, and comprising a small proportion only of animal food. Late in the disease, when the urine becomes scanty, and dropsy or indications of uræmia present themselves, the promotion of urine and drastic purgation are called for.

In all forms of chronic Bright's disease special symptoms require to be treated as they arise. For dropsy the most effectual remedial measures

have already been enumerated. But when the accumulation of fluid is extreme it may need to be removed by surgical means. For this purpose 'acupuncture,' or the puncture of the skin with a needle in several places just above the ankle, or in the scrotum, or some other dependent part, may be performed, or incisions may be made in the same localities. Or, better still, a fine trocar and cannula (according to Dr. Southey's suggestion) may be inserted, and retained *in situ* for some days without inconvenience. It must not be forgotten, however, that erythema and sloughing are apt to follow these slight operations, apparently from the irritating effects of the escaping serum on the integument over which it flows. To avert this danger it is well to anoint the surface previously with sweet oil. Uræmic poisoning may often be obviated or cured by the use of drastic purgatives, or bleeding. The subcutaneous injection of hydrochlorate of pilocarpine in  $\frac{1}{4}$  to  $\frac{1}{2}$  grain doses, which causes profuse sweating, may be similarly useful. When convulsions are present the inhalation of chloroform often affords relief. It is needless to lay down rules with regard to the treatment of uræmic asthma, uræmic dyspepsia, and the many other complications of chronic Bright's disease.

In all cases when either convalescence is in progress or the symptoms are of a chronic character, hygienic and tonic treatment is of the highest importance; and especially residence in a genial climate, moderate out-of-door exercise stopping short of fatigue, wholesome unstimulating diet, and early hours are likely to be beneficial.

In conclusion it may be pointed out that in all varieties of Bright's disease the use of certain drugs is fraught with danger. Of these, mercury, and cantharides are the most important examples. Opium, also, is generally regarded as dangerous; and no doubt it is a remedy which should be employed with caution. But Dr. Stephen Mackenzie has shown that it may be given with great benefit in some forms of uræmic poisoning, especially those attended with breathlessness, palpitation, nausea and sickness, headache or sleeplessness. We also have given it in some such cases with marked relief.

---

## VI. CONGESTION OF THE KIDNEY

*Causation.*—Congestion is present in a greater or less degree in all inflammatory affections of this organ, in many febrile diseases, and as a consequence of the action of certain irritant poisons. The form of congestion, however, which we are now about to consider is that passive congestion which arises in the course of obstructive cardiac and pulmonary diseases.

*Morbid anatomy.*—This condition is characterised in its early stage by congestion, enlargement, and softening of the kidneys. The veins are especially overloaded, and more particularly the stellate veins of the outer surface and those of the medulla. If the congestion continue, induration takes place, due to slow increase of the interstitial fibrous tissue of

the organ, and ultimately atrophy of the Malpighian bodies and of the other secreting elements, including fatty degeneration of the cortical epithelium.

*Symptoms.*—In this affection there is not generally much to attract attention to the condition of the kidneys beyond scantiness of urine, and the presence in it of albumen, and occasionally of blood, and of casts which are hyaline or granular, or formed in part or wholly of disintegrating blood-corpuscles. The albumen is generally scanty, but sometimes very abundant. The specific gravity is usually high. Inflammation readily supervenes. As a rule the general symptoms due to renal congestion are so inextricably intermingled with those of the disease to which the congestion itself is due, and which in fact they closely resemble, that they do not admit of separate recognition. Occasionally, however, uræmic poisoning and other common consequences of Bright's disease are distinctly developed.

The *treatment* is mainly that of cardiac or pulmonary disease, as the case may be; and the employment of remedies calculated to relieve renal congestion, more especially purgatives, diaphoretics, and unirritating diuretics.

## VII. TUBERCULAR DISEASE OF THE KIDNEY

*Morbid anatomy.*—For the most part tubercles are developed in the kidney as a comparatively late event of general tuberculosis, give rise to few or no symptoms, and are of little clinical importance. Sometimes, however, tuberculosis is primary in the kidneys, or at all events may be found post mortem to be as far advanced in these as in other organs; and under such circumstances the renal affection is a material, possibly the chief, item of the patient's illness. When tubercles are abundant and far advanced in the kidneys, they are probably always present also in the mucous membrane of the urinary organs—pelves, ureters, and bladder—and even in the vesiculæ seminales and testes, or in the uterus and Fallopian tubes.

Tubercles appear in the first instance as grey granulations scattered mainly in the cortex, but occurring also in the medulla. It is in this form that they are generally discovered. After a while they increase in number and in size, coalesce into larger masses, undergo caseous degeneration, soften, and perhaps suppurate.

Under such circumstances the kidney may become considerably enlarged, riddled with cavities of various sizes containing cheesy matter, tubercular detritus, or pus, and studded in the intervals with unsoftened tubercles. The destructive process may proceed so far, indeed, that the whole of the secreting structure becomes converted into a series of large tubercular cavities, of which one corresponds to each cone and its associated portion of cortex. These cavities may either communicate by ulceration with the pelvis of the kidney, or remain separated from it, in which

case the contents change after a time into a creamy or mortary material like that already adverted to as due to the drying up of ordinary renal abscesses.

Tubercles affect the mucous lining of the pelvis and ureter in precisely the same way that they affect other such surfaces: miliary granulations appear in scattered groups in the substance of the membrane, become caseous, and then disintegrate, producing shallow circular pits, the surfaces of which generally present more or less tubercular detritus. The junction of neighbouring pits leads to a greater or less extent of superficial destruction, and the formation of an irregular, sinuous-edged ulcer. There is generally also thickening of the subjacent and surrounding tissues. The pelvis generally becomes dilated. The ureter, on the other hand, usually gets narrowed or even obliterated.

*Symptoms and progress.*—In considering the symptoms of renal tuberculosis it is almost impossible to separate them practically from those due to the associated affection of the urinary passages; and it is not difficult to surmise what the main symptoms of these united conditions must be. They are, indeed, essentially those of chronic pyelitis; and comprise pain and tenderness in the loins, tumour possibly, irritability of bladder with perhaps pain or scalding in passing water, and the discharge of urine containing a greater or less abundance of mucus, but more generally pus, albumen, and occasionally, it may be, a little blood, together with debris of tissue. The urine is said generally to be scanty, and not to contain renal casts; but the discovery of casts must not be taken to disprove the presence of renal tubercle, nor is the scanty secretion of urine by any means constant. The reaction of the urine is for the most part slightly acid; but, as in cases of non-specific pyelitis and cystitis, is apt to become alkaline from decomposition. The course of renal tuberculosis is essentially unfavourable; for independently of the slow but sure destruction of the renal tissue, which must ultimately lead to a fatal result, the local disease sooner or later becomes associated with the development of tubercles in other organs. The symptoms and progress of any case will necessarily vary according as the phenomena due to the urinary apparatus or those referrible to implication of other organs preponderate. It is important to bear in mind that the symptoms of renal tubercle and of tubercle of the urinary passages are not in any sense specific; and that their diagnosis must rest mainly on the detection of similar disease in the lungs or elsewhere, or of bacilli in the urine.

*Treatment.*—The treatment of renal tubercle comprises that of tuberculosis and that of chronic pyelitis.

## VIII. SYPHILITIC DISEASE OF THE KIDNEY

Lardaceous infiltration of the kidney is a common attendant on advanced syphilitic cachexia; but specific syphilitic affections of this organ are exceedingly rare. Very few cases of distinct gummatous tumours are

recorded ; but occasionally, on examining the bodies of persons who have suffered from syphilis, and in whom gummata or their remains are visible in other organs, the surface of the kidney presents well-marked linear and stellate depressions corresponding to localised induration and atrophy of tissue. These are most likely of syphilitic origin, but have probably never given any indication during life of their presence. As regards diagnosis, all that can be said is that, when patients with advanced syphilis present symptoms indicative of renal disease, they are probably due to lardaceous infiltration, but may possibly result from the formation of gummata.

## IX. MORBID GROWTHS OF THE KIDNEY

*Morbid anatomy.*—Several varieties of tumour are met with in the kidney. Fibromata sometimes attain a large size—so large, in fact, as to be easily recognisable during life. But they do not, so far as we know, produce any inconvenience or symptoms beyond such as depend on their situation and bulk. The only tumours that have any practical interest are those possessing malignant properties.

1. *Lymphadenoma* generally occurs in the kidney as a secondary or late event in the gradual generalisation of the disease. The renal growth occurs in patches which at the surface of the organ are circular, pale, and scarcely elevated, and are prolonged into its substance in a wedge-like form. Other patches are wholly imbedded in the substance of the organ. On microscopic examination the cells which constitute the growth are found to occupy the intertubular spaces only—the tubules and Malpighian bodies, which may remain healthy, being surrounded and separated from one another by them.

2. *Sarcoma* has occasionally been observed in young children. It is probable, however, that many infantile renal tumours, which have been described as cancerous, were really examples of sarcoma. The disease seems to attack one kidney only, to cause enormous enlargement of the organ, and to be undistinguishable during life from cancer.

3. *Carcinoma* may be primary or secondary. When secondary it rarely attains large dimensions ; when primary it is generally limited to one kidney, and this soon forms an enormous tumour. Renal carcinoma is, almost without exception, of the encephaloid variety, and usually highly vascular. It commences in the form of one or more isolated tumours, which gradually invade the adjacent renal structure until the greater part or the whole of the organ is involved. While this process is going on the kidney enlarges, but still probably on section presents the outlines of its original divisions. With the continuance of the growth, however, all traces of renal structure are obliterated, and the kidney is converted into a simple carcinomatous mass, still probably presenting the form of the healthy organ, but attaining the size it may be of a cocoa-nut or large melon, and weighing several or many pounds. In the progress

of its growth it becomes adherent to surrounding tissues and organs, which may then be involved by continuity; and it develops nodular, papillary, or even villous outgrowths into the cavity of the pelvis and infundibula. The carcinomatous kidney is of course liable to all those changes which generally characterise carcinoma; it presents consequently, in addition to growing tissue, patches or networks of caseous and fatty degeneration, hemorrhagic effusions, and tracts of liquefaction. The ureter is not unfrequently involved, and, even when not distinctly cancerous, is apt to become thickened and occluded.

*Symptoms and progress.*—The recognition of secondary growths in the kidney, whether they be lymphoid, sarcomatous, or cancerous, is a matter of little importance; and that of primary carcinoma is, until the disease is far advanced, often extremely difficult. The chief circumstances to be taken into consideration in forming a diagnosis are: first, the very gradual development of symptoms; second, the frequent discharge of blood in quantity with the urine; third, the gradual formation of a tumour in the situation of the kidney; fourth, the appearance of secondary cancerous growths; and fifth, the occurrence of progressive emaciation, debility, and cachexia. The symptoms, in fact, are mainly those common to cancerous growths, together with such as depend on the situation of the tumour, and on the modification of the urinary secretion. Of these three symptomatic groups the latter two only call for further remark. The development of cancerous tumours is sometimes painless; sometimes, on the other hand, the patient suffers from frequent paroxysms of the most intense agony; and generally sooner or later there is manifest local tenderness. The tumour is characterised by originating deep in the lumbar region, and (as it grows and fills more and more of the abdominal cavity) by its position, its fixation, its general rounded form, and very importantly by the fact that it is almost always crossed by the ascending or descending colon, and has overlapping it, below and to the inner side, portions of the small intestine, the presence of which may sometimes be detected by the eye, and can generally be recognised by palpation or percussion. The veins in the abdominal walls on the affected side are often much dilated; and not unfrequently, from the pressure of secondarily affected glands, œdema of the corresponding lower extremity or of both lower extremities comes on. A cancerous kidney generally feels hard, but is sometimes yielding, and may be so soft as to give a deceptive sense of fluctuation. It often enlarges so greatly as to fill its own side of the abdomen, and occasionally not only fills this, but encroaches to a great extent on the opposite side. It has been pointed out that the urine often contains blood. Hemorrhages occur at regular intervals, and are sometimes so profuse and frequent as to blanch the patient. In many cases, however, no hemorrhage whatever takes place; and in many the urine from first to last is perfectly healthy. The latter circumstance is in great measure due to the fact that the ureter of the affected side often becomes impervious, even at an early stage of the disease. Cancer-cells rarely if ever find their way from the kidney into the discharged urine, and, even

if present there, would probably be undistinguishable from the epithelial cells of the bladder.

The affection with which renal cancer is most apt to be confounded is renal calculus associated with pyelitis and distension of the cavity of the kidney. The liability to error is increased when gravel or small calculi are, as is not uncommon, present in the pelvis of the cancerous organ. In the early stages of cancer, indeed, it is often impossible to discriminate between it and calculous pyelitis. Later on its recognition is more easy, but then the diseased organ is apt to be mistaken for an ovarian, splenic, or hydatid tumour, or for hydro- or pyo-nephrosis.

*Treatment.*—In the treatment of renal cancer there is nothing to be done beyond endeavouring to relieve the patient's symptoms. Opiates are invaluable.

## X. PARASITIC AFFECTIONS OF THE KIDNEY

Animal parasites seldom affect the urinary organs, at any rate in temperate climates. The *Strongylus gigas* and *Pentastoma denticulatum* have been so rarely observed in the kidney that no practical interest attaches to them. Hydatids are much more frequently met with there, and the *Bilharzia hæmatobia* is common in the vessels of the urinary organs in certain tropical countries. Of the *Filaria sanguinis hominis* in relation to the urinary organs we shall speak under the head of chyluria.

A. *Hydatid cysts* of the kidney are far less common than hydatid cysts of the liver. Still, many authentic cases are on record. The anatomical characters, progress, and consequences of renal hydatids present nothing distinctive beyond the facts that the enlarging cysts have the usual situation and connections of renal tumours, and that they not unfrequently rupture into the pelvis of the kidney and discharge their contents with the urine. It must not be forgotten, however, that hydatid tumours may originate in the sub-peritoneal tissue in the neighbourhood of the kidney; and that both these and hydatids occupying other situations may open into the pelvis of the kidney or into the bladder. If suppuration takes place in the cyst of a renal hydatid, the case becomes essentially one of abscess of the kidney.

The *treatment* of renal hydatids is the same as that of hydatids of the liver.

B. The *Bilharzia hæmatobia*, one of the trematoda, is the cause of a form of hæmaturia, endemic in Egypt, at the Cape of Good Hope, and elsewhere. The parasite is of a worm-like form, and three or four lines in length. The female is longer than the male and filiform; the male is comparatively thick, and in the act of copulation encloses the female in a gynæcophoric canal. It is supposed to be swallowed with the food, and thus to gain entrance into the system by the stomach, but it specially

inhabits the mesenteric veins and those of the large intestine, bladder, ureter, and pelvis of the kidney. Its presence in the small veins of the urinary organs gives rise to lenticular patches of inflammation in the mucous membrane, which yield mucus and sometimes blood, ulcerate, and discharge shreds of tissue charged with ova. The patient consequently suffers from irritability of bladder, and passes urine containing these several ingredients. He often falls also into a state of anæmia and debility. When the ureter or renal pelvis is affected, obstruction to the flow of urine may arise, pyelitis and hydro-nephrosis may ensue, and the patient's symptoms may hence assume a more serious character. The ova may form the nuclei of urinary concretions. The presence of these creatures in the mucous membrane of the large intestine is apt to produce dysenteric symptoms, which, however, are rarely severe. The recognition of the disease depends on the discovery of the ova and embryos in the urine.

FIG. 84. *BILHARZIA HEMATOBIA*  $\times 10$  (*Kochanowsky*). (a) male; (b) female grasped in gynaecophoric canal.

*Treatment.*—It is doubtful if vermifuge medicines are of any efficacy in this affection; injections, however, into the urinary bladder may act beneficially on so much of the disease as involves that viscus. The forms of injection which are beneficial in the treatment of thread-worms naturally suggest themselves—namely, bitter infusions, or solution of perchloride of iron. Dr. J. Harley prefers solution of iodide of potassium. For general treatment, tonic remedies are indicated.

## XI. LARDACEOUS DEGENERATION OF THE KIDNEY

*Causation.*—The causes of lardaceous degeneration of the kidney are the same as those of lardaceous degeneration of the liver and other organs; and indeed the liver, kidneys, and spleen are generally concurrently affected.

*Morbid anatomy.*—The lardaceous kidney increases in size with the amount of degeneration present, and may attain a weight of twelve ounces or more. If the disease be little advanced it is apt to escape recognition by the naked eye; when, however, it reaches a high degree, the organ is somewhat waxy, pale and homogeneous in texture, and presents a slight degree of translucency. The morbid change usually commences in the vessels of the Malpighian tufts, but very soon spreads from these to the afferent and efferent vessels, the intertubular plexus, the interlobular

arteries, and the vasa recta. The hyaline walls of the urinary tubes and Malpighian bodies also suffer, but for the most part somewhat later than the vessels. The degeneration here is always most advanced in the large collecting tubes, and diminishes in degree as one proceeds from these to the Malpighian capsules, which in fact generally remain unaffected. The epithelial cells are rarely if ever involved, but are often granular, and even distinctly fatty. Lardaceous change is apt to be superadded in the course of ordinary fatty and granular degeneration of the kidney, in which case the several morbid conditions are variously intermingled. Waxy casts may generally be detected in both the cortical and the medullary tubules.

*Symptoms and progress.*—The presence of lardaceous change in the kidney does not necessarily give rise to any special symptoms until the disease is far advanced. The symptoms then, if not of themselves distinctive, become distinctive when the history of the patient, the condition of his other viscera, and his general state are all taken into consideration. They are mainly as follow: the urine is increased in quantity, pale, of low specific gravity, and poor in urea; it contains albumen, sometimes in large quantities, and casts which have not necessarily any special character, but are often waxy, yet rarely if ever lardaceous; micturition is generally frequent; there is often some degree of anasarca, but it is not usually abundant; and the patient is anæmic. In these respects the symptoms are not unlike those due to the granular kidney; but the heart does not become hypertrophied; there is absence of arterial tension; there is little tendency to uræmic poisoning; and although patients often suffer from serous inflammations, inflammation of the lungs, diarrhœa, vomiting, and hemorrhages, these complications are not distinctly referrible to the kidney disease, but are due in part or wholly to the presence of associated visceral lesions.

The *treatment* of lardaceous kidney is involved in the treatment of the affections to which it is secondary. Dropsy and other consequences, when they are sufficiently serious to demand separate attention, must be treated according to the principles already enunciated under the head of chronic Bright's disease.

---

## XII. GRAVEL AND RENAL CALCULI

*Causation and morbid anatomy.*—The presence in the urine, or the deposition from it, of uric acid and urates, of oxalate of lime or of phosphates, is occasionally observed in various morbid conditions of the system, and even in states of apparently good health. Such occurrences rarely if ever call for medical interference.

Occasionally, however, the appearance in the urine of one or other of these, or of other rarer crystalline matters, persists for some time or becomes habitual. If under such circumstances symptoms of ill-health manifest themselves, medical treatment is obviously demanded; and,

indeed, even in the absence of symptoms, the danger of the formation of urinary calculi is so great that, if the peculiarity of the urine be recognised, it should, if possible, be counteracted.

The amorphous urates are sometimes found deposited in the renal tubules, but this is probably a post-mortem phenomenon only. Urate of soda, in stellate masses of acicular crystals, is now and then discovered imbedded in the substance of the kidney; uric acid also, in solitary or clustered crystals, is occasionally detected within the tubules, and again, in the form of small calculi, is sometimes found loose in the cavity of the kidney or adherent to the mammillary processes. The same may be said in regard to the infinitely rarer xanthine and cystine concretions.

Octahedra and dumb-bells of oxalate of lime, singly or in groups, may be met with in the urinary tubules, and occasionally also form small calculi, which lie loose or adherent within the cavity of the kidney.

The phosphates are rarely deposited, except in ammoniacal urine, and as a consequence of the decomposition of that fluid; they are, therefore, seldom if ever detected in the kidney except as secondary deposits around nuclei of other matters. Carbonate of lime, however, though much less frequently forming a urinary deposit, is occasionally met with in the form of small laminated globular concretions, either imbedded in the substance of the kidney, or free in its pelvis.

The minuter concretions above described are sometimes discharged with the urine in considerable abundance, constituting what is called 'gravel.' Small calculi, from the size of a pin's head to that of a horse-bean, are also not unfrequently transmitted, with more or less delay, along the ureter to the bladder, and thence into the chamber-pot. Sometimes a solitary calculus is thus discharged, and there is never any recurrence; sometimes large numbers of calculi are discharged at intervals. In other cases these bodies remain in the renal cavity, gradually grow there, and finally, perhaps, form a complete cast of the pelvis, infundibula and calyces; or a considerable number of small calculi may become aggregated into that form.

The presence of calculi in the kidney generally induces pyelitis, and probably at length abscess, hydro-nephrosis, or some other serious consequence.

*Symptoms and progress.*—The symptoms of 'gravel' are: pain of an aching or burning character in one or other lumbar region or side of the abdomen, probably shooting down to the testis or labium, and along the inner aspect of the thigh; frequent desire to micturate; soreness or cutting pain during micturition, especially at the end of the urethra in passing the last few drops; and nausea and sickness. At the same time the urine generally is clear, though it may deposit a greater or less abundance of a sand-like sediment, or show microscopic aggregations of crystals, with epithelial scales. The pain may of course affect both sides; and the patient's complaint may be limited to lumbar or abdominal pain or uneasiness.

A renal calculus may never reveal its presence by symptoms, and may

even lead to the disorganisation of the kidney without the least suspicion of disease having ever been excited. The special indications of the presence of a calculus are : first, the occasional occurrence of aching or burning pain in the situation of the kidney, resembling, but probably more severe than, that attending the passage of gravel ; second, the occasional discharge of bloody urine ; and, third, the facts that the nephralgia and hæmaturia are often induced by anything that jolts the body, such as riding, jumping, and other forms of exercise, and that the pain may occasionally be relieved by change of posture. This becomes much more intense when the calculus enters the ureter, and continues intense as long as the stone is passing along that canal. The pain of renal or ureteric calculus may be traced along the ureter, shooting thence into the loin, radiating throughout the abdomen, and especially extending to the thigh and labium or testis, which last often becomes retracted ; it is attended with nausea and vomiting, and not unfrequently with rigors and faintness. It is often increased by the patient's voluntary attempts to flex the thigh on the abdomen. Further, tenderness may exist in the loin and along the course of the ureter. The pain due to the transmission of a calculus begins suddenly, and ends suddenly in a few hours, or after intermissions in the course of a few days, in consequence of the stone becoming either arrested in its course or discharged into the bladder. It need scarcely be said that the microscopic investigation of the urine often throws important light on the diagnosis of cases which come under treatment ; and further, that when one kidney has already been destroyed or rendered useless, the impaction of a stone in the opposite ureter may cause fatal suppression of urine. The symptoms of pyelitis, renal abscess, and hydro-nephrosis, which are frequent accompaniments or consequences of renal calculus, are elsewhere discussed.

*Treatment.*—The treatment of gravel and of renal calculus is for the most part identical with that of pyelitis—a subject which has already been fully considered. The pain, however, in so-called ‘nephritic colic’ is generally so much greater than in other forms of pyelitis that opium, rest, and local measures are all more urgently needed. Opium, especially, is our sheet-anchor. As valuable adjuvants we may enumerate purgatives, copious enemata, ice-bags, hot applications or cupping to the loins, and especially the hot bath. Belladonna is sometimes useful when opium fails ; and, when a calculus is descending, may be of special service in relaxing the spasmodic action of the ureter which takes place around it and impedes its progress. The removal of renal calculi by operative measures can scarcely be attempted unless the proof of their presence be afforded by the abundant or persistent escape of blood or pus with the urine, or there be a manifest tumour in the loin. The removal of renal calculi, however, and indeed the extirpation of the kidney, are now common and often successful surgical operations.

In the intervals between the acute attacks, which, from their severity, call for special treatment, the question of the removal of the conditions on which the gravel or calculi depend presents itself for consideration. Our

action here must be determined mainly by the nature of the sabulous matter which is habitually discharged.

If uric acid crystals or gravel are passed, it is certain that the urine is abnormally acid, and the exhibition of alkalies is demanded. The carbonate, acetate, and citrate of potash are probably the best for the purpose; and they should be given in such quantities as to render the urine constantly alkaline. Sir W. Roberts has shown that the alkaline carbonates slowly dissolve uric acid calculi, and that the urine may be rendered and kept sufficiently charged with carbonate to produce this effect by administering to the adult forty or fifty grains of the acetate or citrate in 3 or 4 oz. of water every three hours. And hence he recommends that, if there be reason to believe that uric acid calculi are present in the kidney, the patient should be submitted to this alkaline treatment. Phosphate of soda also dissolves uric acid, and Dr. Golding Bird recommends its use in scruple or half-drachm doses. It is important at the same time to have regard to the patient's mode and habits of life and to any morbid conditions which may be present. Thus, valuable indications for treatment may be furnished by the fact that he is a *bon vivant* or of sedentary habits, or that he suffers from indigestion or gout.

Cystine and xanthine deposits and calculi may be treated in the same manner as those of uric acid.

Oxalate of lime, like uric acid, is generally precipitated in acid urine, and indeed they are not unfrequently associated. Its presence in small quantity is often dependent on the use of certain articles of diet; when it is more abundant and persists, the patient frequently suffers from indigestion, or presents symptoms of mental depression. The direct treatment of oxaluria is not generally very efficacious. The patient's general health should be improved by tonic medicines and general tonic treatment, and by abstinence, as far as possible, from vegetables containing oxalate of lime, and from sugar and other substances which are readily convertible into oxalic acid. Nitro-muriatic acid is often recommended; while, on the other hand, alkalies seem sometimes to be efficacious.

Persistent alkalinity of urine from the presence of the fixed alkalies is rare and in itself not very important. It generally seems to be associated with some degree of ill-health and cachexia, and may be taken to indicate the need of tonic treatment and of generous diet. Mineral acids, especially the nitro-muriatic, and perchloride of iron, are valuable remedies.

Alkalinity from the presence of carbonate of ammonia is a much more serious matter. This always results from decomposition of the urine in the urinary channels, is indicative of cystitis or pyelitis, and necessarily leads to the deposition of crystalline phosphates. For the relief of this condition we must have recourse to the usual treatment of cystitis.

---

## XIII. HYDRO-NEPHROSIS AND ATROPHY OF THE KIDNEY

*Causation and morbid anatomy.*—Whenever any permanent impediment to the flow of urine occurs (whether it be in the urethra, bladder, or ureter; whether it be due to a calculus or any other obstacle within, or to some affection of the walls themselves, such as thickening and contraction, valvular folds or paralysis, or to pressure from without, caused by ovarian, uterine, or other tumours), the cavities above the seat of obstruction dilate and their parietes thicken, and at the same time the kidney structure becomes expanded and attenuated. The condition known as hydro-nephrosis results. If complete obstruction take place, excretion of urine continues for a time; but its accumulation causes more and more distension of the renal cavity, and more and more pressure on the renal structure, until at length the function of the organ ceases absolutely to be performed. In this case, equally with that in which pus accumulates, those portions of the renal cavity whose lining membrane is least resistant expand most; and consequently, while the pelvis and infundibula alter comparatively little, the calyces dilate until they form a series of sub-globular cavities surrounded and separated from one another by atrophoid kidney structure, and communicating by separate and comparatively small orifices with their respective infundibula. When the obstruction is partial, as well as during that period of total obstruction in which the renal elements are still excreting urine, this fluid changes in quality; it becomes less and less rich in solid constituents, pale, watery, and of low specific gravity, but remains for the most part devoid of albumen. Subsequently to the cessation of the proper urinary discharge, the fluid in the cavity may still increase in quantity and still undergo changes. Thus in advanced hydro-nephrosis it is generally watery but still containing traces of the urinary solids; often albuminous; sometimes charged with decomposing blood; sometimes glairy and colloidal; occasionally purulent. After a kidney has become completely hydro-nephrotic and ceases to secrete urine, various consequences may ensue. In some cases it remains for a long while almost stationary. In some the contents are slowly absorbed and the atrophied tissues shrink and indurate, until at length a small, hard, lobulated cystic body, weighing perhaps from a drachm or two to half an ounce, remains. In other cases the dropsical kidney gradually enlarges until it forms a tumour several times the bulk of the healthy organ, and occasionally sufficiently large to fill at least one-half of the abdomen. Hydro-nephrosis from total or partial, and often valvular, obstruction of the ureter is not unfrequently congenital, and at the same time double; and hence hydro-nephrotic tumours are not altogether uncommon in new-born babes and young children.

*Symptoms and progress.*—As a rule the changes above described creep on (if no inflammation ensue) without producing symptoms, and without, therefore, calling for treatment. It is comparatively rare for the hydro-nephrotic kidney to become so large as to excite observation; still more

rare for it to become so large as to exert by its pressure on surrounding organs any deleterious influence. But in these cases alone is diagnosis needed or indeed possible. The elements on which an accurate opinion must be based are the history of the case, the situation and relations of the tumour, its characters as to form, resistance, and fluctuation, and the constitutional symptoms which are associated with it. In addition to these there is a very characteristic symptom peculiar to cases of incomplete obstruction—namely, the occasional rapid but temporary subsidence of the tumour, attended with a sudden increase in the quantity of urine passed, and some change in its quality. In some cases the dilated organ suppurates, and a renal abscess with the usual symptoms of that condition supervenes.

A hydro-nephrotic tumour is liable to be confounded with carcinoma and hydatids of the kidney or neighbouring parts, and with ovarian cysts. It is rarely fatal, except in those cases in which it is double, or where it is associated with other maladies, or where, from its bulk and interference with other organs, or from suppuration, slow exhaustion ensues.

*Treatment.*—The treatment is entirely surgical. If manipulation fail to drive the contents into the bladder, paracentesis may become necessary. To prevent danger from escape of fluid into the peritoneum this operation should be performed behind the line of colon which crosses the tumour.

#### XIV. MISPLACED AND MOVABLE OR FLOATING KIDNEYS

*Causation and morbid anatomy.*—Misplacements of the kidneys are chiefly important in relation to the diagnosis of abdominal tumours. Sometimes as a congenital peculiarity one or both kidneys, instead of occupying their usual site, lie upon the brim of the pelvis. Sometimes one or both of them, though otherwise normally placed, are attached to the lumbar region by a peritoneal duplicature or mesonephron analogous to the mesentery, or lie freely movable in the lax retro-peritoneal connective tissue which surrounds them. Mobility of the kidney is said to be much more common in women than in men, and on the right than on the left side. Its cause is obscure. It may perhaps in some cases be a congenital defect; but it seems also occasionally to follow upon parturition, and possibly then to be connected with that general laxity of the abdominal parietes which parturition causes.

There is still considerable doubt on the part of many with respect to the occurrence of floating kidney. The question has, however, been set at rest affirmatively by an inquiry made a few years ago for the Pathological Society,<sup>1</sup> and by numerous more recent clinical and anatomical inquiries.

*Symptoms.*—The floating kidney projects more than natural, generally assuming an oblique position with the upper end pointing forwards and

<sup>1</sup> 'Path. Trans.' vol. xxvii. p. 467.

inwards, and is freely movable within narrow limits under the abdominal parietes. Sometimes it forms a perceptible tumour only when the patient stands up or reclines towards the opposite side, falling into its place and becoming no more distinguishable when he lies on his back. It may usually be perceived somewhere in the hypochondriac or umbilical region, between the navel and the cartilages of the ribs, but may even be found lying upon the vertebræ. If on the right side, it is apt to make its appearance just below the liver, and to be mistaken for an hepatic tumour. If it be grasped, as it sometimes can be, a sickening sensation is produced, similar to that which results from squeezing the opposite loin; and sometimes, it is stated, a distinct falling in of the corresponding lumbar region, with increase of resonance, may be clearly recognised. It is generally attended with a painful dragging sensation in the loin; and from its prominent and pendulous condition is unduly exposed to pressure or injury, and consequently apt to become painful, tender, and swollen. It may even suppurate.

*Treatment.*—When a movable kidney is painful, rest, local applications, and the internal use of sedatives may be requisite. To protect it from injury, and at the same time to replace it to some extent, an abdominal belt may be worn, with a concave pad beneath it, adjusted to the form and position of the kidney.

---

## XV. CHYLURIA (*Chylous Urine*)

*Causation and symptoms.*—This affection was first recognised and described by Dr. Prout, but since his time has been pretty frequently met with and investigated by other observers. It is characterised for the most part by the occasional or constant discharge of urine which is milky when passed, coagulates on standing into a tremulous mass resembling blanc-mange, and then, becoming again liquid, furnishes a creamy scum and a pinkish or brownish sediment. The urine has, in fact, exactly those characters which would result from the admixture in varying proportions of normal urine and normal chyle. It presents the ordinary urinary constituents, but in diminished proportion to the whole bulk of fluid. And it also contains fibrine, the presence of which explains its spontaneous coagulability; albumen, as may be shown by the usual tests; fat in a molecular form, like the fat of chyle, the presence of which accounts for the milky character of the fluid when passed, and for the creamy scum; leucocytes, and occasionally red corpuscles, to which the coloured sediment is partly attributable. No casts, however, are ever detected in it; nor indeed is there any other evidence that the chylous material comes from the kidney. Further, it often happens in these cases that the urine which is passed is not milky, although probably presenting in all other respects the peculiarities which have been enumerated. It is, in fact, lymphous, and not chylous; there is no fat, and the coagulum is transparent like ordinary calf's-foot jelly. The presence of fat is, in some instances, observed

mainly in the morning's yield ; more commonly it characterises the urine passed shortly after meals.

Chyluria appears to be more common in tropical than in temperate climates, more frequent in adults than in children, and in females than in the opposite sex.

It manifests itself, for the most part, suddenly ; is liable to intermissions ; and occasionally, after lasting some time, disappears for years or even for life. It is attended with no special symptoms, excepting such as may result from the continuous drain of nutrient fluid, and those directly connected with the condition of the urine and urinary organs ; and its presence is compatible with apparent good health, and even with long life. The characters which the urine presents have already been described. It may be added that chylous urine not unfrequently coagulates in the bladder, causing more or less discomfort and the discharge of coagulated material.

*Pathology.*—Dr. Prout attributed the disorder to a combination of two circumstances : one a defect of assimilation which permits chyle to mingle with the blood without being converted into blood ; the other some renal default, in consequence of which unchanged chyle is allowed to sweat from the kidneys. But the blood has been examined in cases of chyluria without the detection of any abnormal chemical constituent in it ; and not only, as has already been stated, is there no evidence during life to show that the kidneys themselves are diseased, but post-mortem examination equally fails to detect any structural change in them.

Sir W. Roberts, basing his views partly on a case recorded by himself, and partly on one published by Dr. Vandyke Carter, suggested some years since an explanation of the phenomena of chyluria which, so far as it goes, seems to be correct for at least many cases. In these two examples there was chyluria, but there was also on the lower part of the abdomen and on the scrotum enlargement of lymphatic vessels, with vesicular dilatations, which yielded abundance of lymph or chyle—exactly the same kind of fluid as that which was passed with the urine. In Dr. Carter's patient, the discharge of chyle from the urinary organs and that from the skin alternated. Sir W. Roberts contended that in these cases the chyle in the urine and that yielded by the skin were derived from a common source—namely, rupture of vesicular dilatations of lymphatic vessels situated on the one hand in the mucous membrane of the bladder or that of some other part of the urinary tract, on the other hand at the cutaneous surface ; and he thence argued that chyluria generally depends on a similar lymphatic affection of the mucous membrane of the urinary tract. The disease, in fact, from this point of view, is identical with what has been described earlier in this volume under the name of elephantiasis lymphangiectodes. Many other cases of this association have since been recorded. In a case of Dr. Stephen Mackenzie's<sup>1</sup> of combined chyluria and filarial disease, in which death resulted mainly from double pleurisy and empyema coming on (concurrently with a total disappearance of

<sup>1</sup> *British Medical Journal*, May 20, 1882.

filariæ from the blood) three months before that event, there were found acute cystitis and suppurative nephritis in an early stage. But also the thoracic duct was impervious and lost in a mass of inflammatory material about the middle of its course; the part below, together with the abdominal lymphatics and those connected with the kidneys, being enormously dilated. No filariæ were discovered. But there was reason to believe that the parent worms had been lodged in the thoracic duct, had caused the inflammatory mischief and obstruction, and hence the general dilatation of lymphatics; and that the chyluria was connected with the enlarged state of the lymph-channels in the substance of the kidneys.

We have already discussed the interesting discovery by Dr. Lewis of the *filaria sanguinis hominis* in the urine, diseased tissues, and blood of patients suffering from chyluria and spurious elephantiasis in India; and have shown that there is good reason to believe that the parasite is (at any rate in many cases, possibly in all) the essential cause of these two affections; the frequent association of which is thus plausibly explained.

*Treatment.*—It is needless to enumerate all the remedies that have been employed in the treatment of chyluria; nothing appears to have ever been really efficacious, and it is clear, if the explanation above given be correct, that nothing, except perhaps rest and astringents locally applied, is likely to be efficacious. Tonics may be needed in the anæmia which is apt to come on in the course of chyluria.

## XVI. HÆMATURIA

*Causation and symptoms.*—The presence of blood in the urine may be due to many different circumstances, but these have already been discussed in sufficient detail, and need not be further considered now.

It is not always possible to ascertain the source or the cause of hæmaturia. It may, however, be observed that, if it take place from the substance of the kidney, it will almost always be attended with the presence of blood-casts, and the urine will generally be more or less smoky; that, if it take place from any of the urinary passages, no casts will be present; and that, if it be derived from the bladder or urethra, pure unmixed blood will probably be occasionally passed, either at the commencement or at the end of micturition, or at other times. Further, the more abundant the blood is, and the more it exhibits the ordinary characters of blood and tends to coagulate, the more likely is it to have been yielded by the urinary passages. The hemorrhage which attends simple congestion or inflammation of the kidneys or urinary channels is generally scanty. The most profuse hemorrhages are usually due to villous or malignant growths of the bladder or kidney, or to the effects of renal or vesical calculi. Profuse hemorrhage is said also to occur vicariously of menstruation. We have previously described the appearance which the urine presents when mixed

with blood ; and we must refer the reader to other parts of this chapter for an account of the lesions of the urinary organs liable to be attended with hemorrhage, and for the means by which their respective hemorrhages may be distinguished.

*Treatment.*—When the discharge of blood with the urine is scanty and of temporary duration, the loss in itself is a matter of little importance, and no special anti-hemorrhagic treatment is needed. But persistent small hemorrhages, as well as occasional profuse hemorrhages, require if possible to be arrested. The patient should be placed in the recumbent position, and kept perfectly quiet and cool. He should have ice to suck, or be supplied with cold drinks in small quantities. In addition, it is advisable to give by the mouth astringent medicines, such as turpentine, gallic acid, or other vegetable astringents, lead, perchloride of iron, or a mineral acid. But probably more valuable than any of these is ergot or digitalis. If there be reason to believe that the bleeding is taking place from the kidneys, ice or cold compresses may be applied to the loins ; if from the bladder, similar applications may be made to the perineum or hypogastrium, and either cold water or solutions of perchloride of iron or tannic acid may be injected into the bladder.

## XVII. PAROXYSMAL HÆMOGLOBINURIA (*Paroxysmal Hæmatinuria and Hæmaturia*)

*Definition.*—This interesting affection, which is now fully recognised and often met with, was first described a few years since by Dr. G. Harley. It is characterised by the sudden occurrence, at irregular intervals, of febrile paroxysms attended with the discharge of urine more or less abundantly loaded with the colouring matter of the blood and albumen, but without any presence of blood-corpuscles.

*Causation.*—Paroxysmal hæmoglobinuria has hitherto been observed almost exclusively in males, and for the most part between the ages of 20 and 40. It may occur, however, at any age, and even in young children. In a few of the recorded cases the patients had previously had attacks of ague ; and it is certain that many suffer, or have suffered, from symptoms of Raynaud's disease. But, for the most part, the affection comes on in persons in whose previous medical history there is nothing to throw light on its causation. In all cases the onset of the disease is sudden, generally in cold weather, and, so far as we know, distinctly traceable to some undue exposure to cold.

*Symptoms and progress.*—The patient, immediately after exposure, or in the course of it, complains of chilliness, and uneasiness across the loins—the latter condition sometimes passing into severe aching, the former into a more or less profound sense of cold, attended with pallor or duskiness of surface, shrinking of the skin and rigors. Together with these symptoms there may be general weakness, stiffness and aching in the limbs, yawning, nausea, vomiting, and retraction of the testicles. During the exposure

the temperature of the body may have become subnormal; but with the onset of symptoms it begins to rise, attains its highest point in the course of one or two hours, and then gradually falls. Shortly after the commencement of the attack the patient is astonished to find on passing water that this fluid is dark-coloured and turbid or porter-like. It continues thus for an hour or two, or more, and then gradually returns to its normal condition. After the febrile disturbance has reached its highest point, the symptoms all gradually abate, and in the course of a few hours the patient, for the most part, appears to be perfectly well.

The extreme elevation of temperature varies in different cases from about  $99^{\circ}$  to  $105^{\circ}$ , and is attained in the course of two or three hours; after which the temperature falls, the whole duration of the febrile attack being generally about five hours.

The urine first shows evidence of the presence of hæmoglobin in from half an hour to three hours after exposure to cold. There is reason to believe, however, that in most cases such evidence would be shown in the course of half an hour, if the contents of the bladder at that time were voided. The urine for the most part is dark-coloured and turbid, and deposits a chocolate-coloured grumous sediment. But it varies in different cases and in different periods of the same attack. Thus sometimes it is clear and transparent, without sediment, and of colour varying from that of brown sherry to that of port. The grumous deposit is mostly amorphous, but it may contain granular or hyaline casts of the renal tubules, and sometimes presents crystals of oxalate of lime or of hæmatin. There is a total absence of blood-corpuscles. The abnormal constituents of the urine are: first, albumen in variable quantity, of which a portion at any rate appears to be the albuminous constituent of the red corpuscles, and amorphous hæmoglobin, with which are sometimes associated more or less met-hæmoglobin and more or less acid-hæmatin. Dr. Copeman's investigations show conclusively that the colouring matter as excreted is oxy-hæmoglobin, but that retention of the urine in the bladder, or in the chamber-pot, is attended with more or less conversion of this into met-hæmoglobin and acid-hæmatin. The urine continues for two or three hours to be excreted in the condition above described; it then gradually reverts to the normal state, which it very often does not attain until some two or three hours after the patient is in other respects quite well. It is an important and interesting fact that occasionally, when the attack is also in other respects mild, hæmoglobinuria is replaced by the temporary discharge of albumen alone. The urine is generally acid, and its specific gravity varies from about 1015 to 1030.

Other symptoms which the patient sometimes experiences during the progress of his attack are: 'dying' of the fingers, toes, or other regions of the body; tingling in the same parts and in the tip of the tongue; aching in the throat, and difficulty in swallowing.

The onset of subsequent attacks is equally sudden with that of the first; and the succession of events is for the most part repeated in all of them. Moreover, the later attacks, like the first, are generally dis-

tinety traceable to the influence of cold, the slightest exposure being in many cases competent to evoke them. They come on at irregular intervals, and mostly, as has already been stated, in cold weather. And they may continue off and on for many years, not only without causing disease of the kidneys, but without materially affecting the general health. Patients, however, are apt to become languid and weak and (especially after attacks) anæmic; to present a sallow or slight icteric tint; and to manifest, as in other cases of anæmia and in aortic regurgitation, the phenomenon of capillary pulsation.

*Pathology.*—It seems to have been clearly established that paroxysmal hæmoglobinuria is due to the direct influence of cold upon the red corpuscles of the blood; that these bodies, under the influence of cold, break down in large proportion, yielding up their albuminous constituent and hæmoglobin, which diffuse themselves through the plasma, and then become rapidly eliminated by the kidneys, thus rendering the urine albuminous and blood-stained. The injurious effect of cold on the blood in these cases has been proved both experimentally and by clinical observation. After a comparatively brief experimental exposure it has been found that the blood-corpuscles have undergone a reduction of between 129,000 and 824,000 in the cubic millimètre, and that the remaining corpuscles have become altered in size and shape, and the plasma not only tinted with the diffused colouring matter of the corpuscles but also presenting granular masses of hæmatin. The destruction of red corpuscles in the blood is constantly going on as a normal process, under which circumstances their constituents become disposed of in the manufacture of the colouring matters of the bile and urine, and in other ways. But in this disease their destruction is far too rapid and too great to permit of their utilisation in any large degree in the normal physiological processes, and the excess consequently becomes eliminated by the urine. It is an interesting fact that, as has been already pointed out, when the attack is slight and the destruction of corpuscles comparatively little, the liberated hæmoglobin is in fact disposed of in the organism, and temporary albuminuria alone ensues. It will be recollected that albumen occasionally appears in the urine of persons not supposed to be suffering from hæmoglobinuria, after cold-bathing or other kinds of exposure to cold. The relations of hæmoglobinuria to pernicious anæmia and to Raynaud's disease have already been adverted to in the articles on these diseases. As regards Raynaud's disease, while admitting their frequent association, we entertain no doubt that the only relation between them resides in the fact that the phenomena of both are largely induced by the influence of cold. But hæmoglobinuria is a disease of the blood or blood-forming organs; the other is an affection of the arterial walls, or probably rather of the nerves regulating their action. The kidneys are certainly not the seat of disease in hæmoglobinuria. They are merely passive agents in removing the products of the disintegration of the red corpuscles.

*Treatment.*—Many remedies have been employed, but none with any striking success: quinine and arsenic on the ground of the periodicity

which the disease presents; iron because of the patient's anæmic state; perchloride of iron, gallic acid, and lead for their styptic properties; and digitalis and ergot of rye on account of their influence in contracting the arterioles. The most important treatment, however, is the prophylactic. During the paroxysm the patient should be placed in bed and kept warm; and at other times he should be cased in flannel and otherwise warmly clad, his feet and loins especially should be protected, and he should carefully avoid all exposure to draughts, all loitering in the cold, and riding in cold weather in an open vehicle. In severe and intractable cases the question of permanent residence in a warm climate, or at any rate of passing the winter months in such a locality, should be considered.

### XVIII. DIABETES (*Diabetes Mellitus. Glycosuria*)

*Definition.*—The most striking phenomenon of this disease is the excretion of urine containing a greater or less amount of glucose or grape-sugar. It is not, however, everyone whose urine contains glucose who can be said to suffer from diabetes. For it has been shown that this substance may be present in the urine temporarily or in small quantities in many affections involving hepatic congestion, such as injuries or organic lesions of the liver, and obstructive cardiac and pulmonary complaints, in certain affections of the central nervous organs, and also under the influence of particular articles of diet; while none of the other special phenomena of diabetes are either present or tend to become developed.

*Causation.*—The cause of diabetes is not known. It is certainly hereditary in some cases; it occurs at all ages, from infancy to old age, and in both sexes, though about twice as frequently in the male as in the female. It has been attributed to exposure, habits of life, injuries of various kinds, and mental disturbance. In most cases, however, no cause whatever can be assigned or suggested.

*Symptoms and progress.*—Diabetes, for the most part, comes on insidiously. The patient perhaps observes, almost by accident, that day by day his urine is getting more and more abundant, his thirst is increasing, his appetite is getting voracious, and yet that he is losing flesh and strength. Occasionally he is also, and possibly first, struck by some peculiarities in his urine, dependent on the presence of sugar in it. He finds, that when drops of it fall upon his trousers or boots, a whitish powdery film is left after evaporation, or that flies, bees, or other insects are attracted to the contents of his chamber-pot, or to surfaces on or against which he has emptied his bladder. The prominent features of the disease are comprised in this brief sketch: they are, the excretion of an excessive quantity of urine loaded with glucose, intense thirst, voracious appetite, together with progressive emaciation and debility, followed after a longer or shorter time by death. These symptoms,

however, present a good deal of variety, and many others of more or less importance are generally associated with them. We will discuss them *seriatim*.

The quantity of urine discharged is generally much larger than natural; so that the patient not only micturates frequently during the day, but is compelled to rise from his bed several times in the night in order to relieve himself. Its quantity depends, of course, mainly upon the quantity of fluid which he drinks, and therefore varies largely. It is sometimes little more than normal, but generally averages between six and twelve pints daily, and occasionally rises to twenty, thirty, or more. The urine is usually of a pale yellow colour, acid, clear and free from sediment, and has a peculiar odour which has been likened to that of new milk, apples, or hay. Its specific gravity, notwithstanding the large quantity passed, is always abnormally high. It is rarely below 1035, often rises to 1045 or 1050, occasionally reaches 1060, and is said to have exceeded 1070. The cause of this density is the presence of an abnormally large proportion of solid constituents. As a rule, considerably more urea is discharged daily by diabetic than by healthy persons; but the amount of urea is usually small in proportion to the quantity of fluid in which it is dissolved. The increase of specific gravity, therefore, is not due to that ingredient. It depends, indeed, almost entirely upon sugar. This varies, of course, considerably in quantity; but generally forms from eight to twelve per cent. of the urine, and ranges from fifteen to twenty-five ounces daily. Its amount may, however, be much less than this, and also much greater. It is greatest after meals, and is always largely increased after the ingestion of sugar or starchy food. Under opposite circumstances it diminishes; and it may disappear absolutely if the diet be restricted to nitrogenous substances. Sometimes, under the influence of inflammatory affections, and again towards the close of the disease, the urine diminishes both in quantity and in specific gravity, and its sugar lessens or fails; sometimes it becomes albuminous, and hyaline casts may be found in it. Dependent in some degree on the irritant effects of the urine, the urethral orifice in the male, or the vulva in the female, becomes red and irritable, and even excoriated or eczematous. The sexual appetite is sometimes augmented in the beginning; but both that and virile power diminish before long, and then disappear.

One of the most distressing symptoms of which diabetic patients complain is extreme thirst; and it is one of the first symptoms to make its appearance. The appetite, too, is generally excessive, often ravenous. This, however, is subject to considerable variation. Sometimes it is no greater than natural, sometimes it is much impaired; and there may even be nausea and absolute loathing of food. The latter conditions often come on towards the termination of the case. The mouth, fauces, and tongue are usually dry, clammy, and morbidly red. The gums are apt to retreat from the teeth, and these latter to become loose and fall out. The patient often complains of uneasiness or sinking at the epigastrium. The bowels usually are constipated, the motions scanty and dry; but occasionally,

and not unfrequently ushering in the fatal event, dysenteric diarrhœa supervenes.

The skin of diabetic patients is almost always dry and harsh, though occasionally slight perspirations occur, and some patients perspire freely. There is often a tendency to itching; and various eruptions, especially eczema, psoriasis, and boils, are said to be of common occurrence. The hair sometimes falls out. The skin, or rather perhaps the patient generally, yields an unpleasant odour, like that characteristic of his urine.

The symptoms referrible to the heart and lungs are merely such as usually attend wasting disease—namely, increasing feebleness and rapidity of pulse, and shortness of breath, especially on exertion. The blood of diabetic patients contains glucose, of which as much as  $\cdot 3$  to  $\cdot 5$  per cent. has been detected by analysis.

Nervous phenomena of various kinds usually manifest themselves in the course of the disease. The patient becomes apathetic, morose, taciturn, or irritable, and towards the close drowsy or comatose. Insanity sometimes supervenes; and occasionally various forms of hyperæsthesia, loss of motor power, and the like. Impairment of vision is also a common incident of the disease; in some cases the patient loses simply the power of adjustment for near vision—becomes prematurely presbyopic; in some he suffers from amblyopia without obvious ocular lesion; while in some soft cataract forms in one or both eyes.

But, besides the above phenomena, others come on which are referrible not so much to any one organ as to general impairment of nutrition and advancing debility. There is great susceptibility to external cold. A sort of hectic condition arises, occasionally attended with febrile elevation of temperature; generally, however, the temperature remains normal or falls a little below the normal. Emaciation is almost constant: the fat disappears, the muscles shrink, the frame becomes attenuated, the skin appears tightly drawn over the forehead and other parts of the face, and is thrown into fine wrinkles when expressional and other movements of the facial muscles are executed. Occasionally, on the other hand, and more particularly in elderly persons, the tissues remain overloaded with fat to the end. Towards the close of the disease anasarca, generally limited to the lower extremities, is of common occurrence. And not unfrequently gangrene takes place in the fingers, toes, or more extensive portions of the extremities, in the genitals, nose, ears, or other parts.

Another complication which is at least as common as any of the above, and on the whole of far more importance, is pulmonary phthisis. This attacks a large proportion of diabetic patients; and indeed of patients who die of diabetes probably one-half suffer from it. The affection is rarely if ever in the form of miliary tuberculosis, but almost invariably in that of caseous consolidation, with tendency to disintegration and the formation of cavities.

In some cases the progress of diabetes is exceedingly acute and rapid. Death has resulted from it after an illness of two or three weeks only. On the other hand, death may be delayed for ten years or more. For the

most part, however, the patient succumbs in from one to three years. Recovery is exceedingly rare. The cause of death usually is asthenia, hastened in some cases by gangrene, dysentery, or phthisis; but not unfrequently the patient dies comatose. Death from coma is one of the most interesting phenomena of diabetes: It occurs mostly in young patients, and in cases of acute progress, and occasionally even before the other symptoms of diabetes have been recognised; sometimes coming on suddenly, sometimes being preceded by premonitory symptoms which vary in details, but amongst the most important and common of which are exhaustion, restlessness, dyspnoea, and severe pain in the epigastrium or loins. But besides these may be enumerated as occasionally present loss of appetite, nausea and sickness, diminution in the amount of urine and in the excretion of sugar, and mental excitement suggestive of alcoholic intoxication. The symptoms of the attack differ somewhat in different cases, but for the most part are those of collapse, on which profound coma presently supervenes. The patient becomes restless, but apathetic; he breathes deeply and noisily, but there is no impediment to the entrance of air into the lungs or to its escape therefrom, and no abnormal auscultatory signs; the heart's action becomes rapid and feeble; the internal temperature falls, and the extremities become cold; his apathy passes into somnolence, and this into profound coma. Death usually follows in from 10 to 48 hours. The occurrence of coma has been attributed to the development of acetone in the blood by fermentation; to the breaking up of the blood-corpuscles due to the effects of acetone or some allied poison; to accumulation of fatty matter in the blood and the formation of fat emboli; and to various other causes. But there is considerable doubt as to the sufficiency of any of the hypotheses which have hitherto been suggested in explanation of the phenomena of diabetic coma. It should be added, however, that diabetic patients bear fatigue, mental or bodily, very badly, and that it is especially after such fatigue that they are apt to fall into the state of collapse and coma above described.

The preceding remarks apply to the usual form of the disease. But in elderly persons, and especially in such as are gouty, the urine not unfrequently contains sugar, it may be in large quantities, and yet few or none of the other symptoms of diabetes are present. The glycosuria under such circumstances may persist for years, either uniformly or with remissions, the patient perhaps passing at times more water than natural, and suffering more or less from dyspepsia, yet presenting no emaciation and no serious impairment of strength, and ultimately recovering, or dying not of diabetes or its ordinary complications but of some independent disease.

*Morbid anatomy and pathology.*—Morbid anatomy reveals little as to the nature and processes of diabetes. Excluding dysenteric affection of the bowels, gangrene of various parts, pulmonary tuberculosis, and cataract (which are not present in all cases, and present no distinctive characters), but little remains for description. The kidneys generally are enlarged and congested, and the epithelial lining of the tubules is occasionally distinctly fatty. The liver and other chylipoietic viscera, to

which on theoretical grounds attention should be mainly directed, present no constant lesions. The former has occasionally been found cirrhotic; the latter inflamed; but far more commonly all appear healthy. The nervous system, again, has been examined with care, on account of the influence which certain parts of it have in causing glycosuria. Tubercular and other tumours have occasionally been discovered in the neighbourhood of the fourth ventricle; and Dr. Dickinson has drawn attention to the existence of small cavities, sometimes visible to the naked eye, originating in softening and degeneration of the tissues around some of the smaller arteries, and containing, when fully formed, simply serous contents. He has found them in most parts of the central nervous organs, but more particularly in the olivary bodies, the median plane of the medulla oblongata, and the grey matter in the floor of the fourth ventricle.

If the pathology of diabetes has not been completely elucidated, it has at any rate had much light thrown upon it during the last few years by the labours of Bernard and other investigators. It has been proved that the liver, besides manufacturing bile, is an organ for the conversion of albuminous and starchy matters (mainly if not entirely those obtained directly from food) into dextrine or glycogen—a starchy substance which exists in large quantities in the liver, and is readily convertible by ferments (and among others by a peculiar albuminous ferment existing in the blood but not yet separated from it) into glucose, or grape-sugar. It is probable that the healthy liver also converts sugar itself into glycogen, and that hence, amongst other duties, the liver opposes a barrier to the admixture of saccharine ingesta with the blood. What becomes of this glycogen, which is formed and accumulates in the liver, we need not stop to consider. Further, experiments made by Bernard, Schiff, and others, have demonstrated the important influence which the nervous system exerts over the glycogenic function of the liver. It has been proved that by irritating various parts of the central nervous organs artificial diabetes may be induced—irritation of the floor of the fourth ventricle, particularly of a spot in it midway between the origins of the auditory nerves and pneumogastrics, being especially efficacious in this respect. There is reason to believe that this spot is either the origin of, or in relation with, the tracts of sympathetic nerves which regulate the diameter of the hepatic vessels, and that through the agency of these nerves the vessels of the liver become actively dilated, upon which phenomenon congestion and glycosuria supervene. Schiff, by dividing the anterior columns of the cervical cord through which the sympathetic tracts above referred to pass on their way to the liver, also produces glycosuria; which, again, is probably dependent on dilatation of the hepatic vessels and hyperæmia, but upon dilatation of paralytic origin, and which, like the diabetes it causes, is of comparatively long duration. Experiments would therefore seem to show: that diabetes depends on dilatation of the hepatic vessels, with accumulation of blood in them and rapid flow of blood through them, and consequently on increased or rather modified functional activity of the liver; and that this dilatation may be either active (the result of

irritation of nerves), producing for the most part a temporary condition of diabetes, or passive (the result of paralytic dilatation), inducing as a rule a chronic form of glycosuria. The dependence of diabetes on hyperæmia of the liver has been demonstrated by other experiments in which hyperæmia has been brought about without the intervention of the nervous system; and is confirmed by the not unfrequent occurrence of some degree of the affection in pathological congestion of the liver, arising from cardiac or pulmonary disease, from injuries to the liver and from inflammation of the organ. According to these views, which it may be remarked only partially explain the dependence of diabetes on hepatic derangement, the occasional and temporary impregnation of the urine with sugar would seem to have an irritative, the typical forms of diabetes a paralytic, origin.

*Treatment.*—The treatment of diabetes is a subject of great interest, and has been regarded and conducted from all points of view with varying degrees of success. As with most other diseases, some cases of it are so serious from the beginning and so rapidly fatal that all efforts to arrest their progress are futile; while some cases are so slightly pronounced that the patients either remain in fair health in spite of their sugary urine, or appear to derive benefit from almost any treatment. Between these extremes lie the great majority of cases, which, if not admitting of cure, undoubtedly often admit of important alleviation by appropriate treatment. It may at once be stated that the use of blisters and other local applications to the head or to the liver has been advocated and practised by various physicians, on the ground that one or other of these organs was at fault; and beneficial results have been recorded. Further, we may at once point out the general importance of promoting the functions of the skin by warm baths and warm clothing; of maintaining the regular action of the bowels; of alleviating, arresting, or curing dysentery and other complications which so frequently attend the progress of diabetes; of preventing all unnecessary fatigue; and of putting the patient under those external conditions which are commonly regarded as conducive to health.

The most important point, perhaps, in the treatment of diabetes is the regulation of the patient's diet. It has long been proved that the abstention from sugar and from those other articles of food which are most readily convertible into sugar is always attended with a marked diminution in the quantity of sugar voided, in the specific gravity of the urine, and in the amount of that fluid secreted; and that in a very large proportion of diabetic patients there is at the same time gain of flesh with manifest improvement of health. For these reasons it is customary to debar the patient from certain alimentary matters, especially sugar in every form, and all vegetables or vegetable products whose nutritious qualities depend on sugar, starch, or related matters—among which may be enumerated bread, potatoes, rice, sago, tapioca, peas, beans, turnips, parsnips, carrots, and most fruits. There is good reason also to believe that alcohol in all its forms is pernicious. Among permissible foods are: first, green vegetables; second,

all sorts of animal food, including milk, eggs, cheese, and butter; and, third, tea and coffee without sugar, but sweetened if need be with glycerine. It is found, however, in practice almost impossible to overcome the craving for bread or some equivalent for bread which soon arises under the use of a restricted diet. Various substitutes have been suggested and may be used temporarily; the most important being gluten bread, bran cake, and almond biscuits or rusks, to which may be added (as being more palatable, though more objectionable) toast uniformly and deeply browned. Dr. Donkin has advocated the administration of skim milk, to the exclusion of all other food. He gives from six to eight pints daily to an adult. And it is certain that many patients in a short time get fairly reconciled to it, that they often gain strength and flesh under its use, and that at the same time the urine diminishes in quantity, in density, and in the amount of sugar it contains.

It has often been held important to restrain the patient from gratifying his intense craving for drink. It is cruel, however, to put such restraint upon him, and of very doubtful benefit. Acidulated drinks are said to be specially useful in assuaging his thirst, and, above all, dilute solutions of phosphoric acid.

Of all drugs, opium seems to be the most efficacious. It has long been esteemed in the treatment of diabetes. Diabetic patients are said to be little susceptible to the influence of opium, and may therefore take it with safety in comparatively large quantities. It is best, however, to commence with small doses, say half a grain, of the powder, three times a day, and gradually to augment them, according to their effect, until each dose is increased to five or six grains. A fair number of cases have been recorded in which great amelioration, if not absolute cure, has followed this treatment. Still more recently Dr. Pavy has employed, and apparently with considerable success, codeia, in doses commencing at about half a grain, three times a day, and gradually increasing to two or three grains. Again, alkalies (bicarbonates, acetates, citrates) have been regarded as valuable remedies; as also has the hot vapour bath. Iron and other tonics are sometimes beneficial.

As respects the treatment of the masked diabetes of elderly people, it is impossible to lay down definite rules. It is generally needless to carry out the plans recommended above, at any rate to carry them out strictly or continuously.

## XIX. DIABETES INSIPIDUS (*Diuresis*)

*Definition.*—Under these titles are grouped a number of cases, which are linked together and characterised by the association of extreme thirst with the excretion of a large quantity of pale limpid urine, free from sugar, and of low specific gravity.

*Causation.*—Diabetes insipidus is rare, but appears to occur at any age and in either sex. The causes to which it has been attributed are

various. Among them may be mentioned tuberculosis, diseases of the brain, drink, accident, and exposure. According to Trousseau and some others, it has a close relation to diabetes mellitus, not only in symptoms but in the facts that there is an hereditary connection between them, and that the former is occasionally a sequela of the latter. Bernard, moreover, has shown that diabetes insipidus, as well as glycosuria, may be produced by irritation of the floor of the fourth ventricle.

*Symptoms and progress.*—This affection comes on sometimes insidiously, sometimes suddenly. Its chief symptoms are the following:—First, the secretion of large quantities of urine: the quantity passed is often considerably larger than in saccharine diabetes; it may be as much as 20, 30, or 40 pints daily, or even twice as much; the urine, moreover, is pale, watery, of low specific gravity (often not above 1002, 1003, or 1004) and containing no sugar or other abnormal ingredient. Second, extreme thirst: this is proportionate to the diuresis, the quantity of fluid drunk being equal or nearly so to the quantity eliminated.

Other symptoms vary. In some cases the patient appears to be well in all other respects, and, except for the continued presence of his infirmity, enjoys life, probably attaining old age. In some cases he presents all the usual indications of diabetes mellitus: he has a voracious appetite, a parched mouth, and dry skin: he becomes anæmic, sallow, emaciated, and weak; and after a longer or shorter time dies as ordinary diabetics die. In other cases, again, diabetes insipidus is from its commencement associated with the presence of tuberculosis or other lesions, and is thus a mere incident or complication of a more serious malady.

*Morbid anatomy.*—In a few cases which have been collected by Sir W. Roberts, the morbid anatomy of diabetes insipidus is illustrated. There is little, however, in the recorded post-mortem examinations to throw light on the nature of the affection. In several of the cases the kidneys were atrophied, and in one hydro-nephrotic. There is some reason to suspect that in these the primary affection was renal. We have known in fact the excessive diuresis of contracted granular kidney to be mistaken for it. In others the kidneys were healthy, as also were they in a case which died under our own care. In this case, as in one of Roberts's, the patient suffered from tuberculosis, which probably caused death. Here undoubtedly the diuresis was symptomatic only. We have met with the disease also associated with syphilitic disease of the brain.

*Treatment.*—There is little to say about the treatment of diabetes insipidus. Various remedies, including tonics and regulation of diet, have been tried. Trousseau and Rayer strongly recommend valerian in large doses. The former commences with two or three drachms of the extract daily, and generally pushes the treatment until the daily portion reaches an ounce. Baths are sometimes beneficial. The constant galvanic current, passed between the loins and epigastrium, has been recommended by Dr. M. Seidel.

---

XX. SUPPRESSION OF URINE (*Ischuria Renalis*)A. *Functional Suppression of Urine*

More or less complete suppression of the urinary secretion, lasting for a longer or shorter period, is not unfrequent in the course of many different diseases or morbid conditions, among which may be enumerated malignant cholera, certain of the infectious fevers, acute enteritis, inflammatory affections of the kidneys, collapse, and hysteria. In many such cases the suppression is symptomatic only, and probably scarcely affects the patient injuriously; in others the retention of urea and other effete nitrogenous matters in the blood which attends the suppression induces or aggravates typhoid phenomena and thus hastens death. It is remarkable, however, how sometimes, and more especially in cases of hysteria, the urine continues for many weeks at a time in almost complete abeyance (the patient going, perhaps, for two or three days consecutively without secreting any, and then perhaps passing only an ounce or two in the course of the twenty-four hours), and yet she remains wholly free from evidence of uræmic poisoning. These several varieties of suppression are considered elsewhere in connection with the diseases in which they occur, and need not further detain us now. In sudden obstruction of the renal arteries, or of the aorta above the giving off of these vessels, the kidneys become congested, and the secretion of urine is, for a time at any rate, suppressed or greatly diminished. In the latter case the urine becomes albuminous, and may contain blood. If the patient survive, the urinary secretion may be re-established, perhaps at the end of a few hours, and may resume its healthy character. For the treatment of the above cases, simple diuretics, more especially copious bland fluids, the use of hot hip or other baths, and the application of counter-irritants to the lumbar region, comprise everything likely to be of real service.

B. *Suppression of Urine from Obstruction*

*Causation and morbid anatomy.*—Another class of cases of so-called ‘suppression’ is that in which the failure to discharge urine depends on the existence of some mechanical obstacle to the escape of urine, situated either in the pelvis of the kidney or, as is far more common, in some part of the ureter. The permanent obstruction of one ureter, its fellow remaining pervious, is, as we have already shown, a not uncommon accident; and on the one hand results in the production of hydro-nephrosis with ultimate wasting of the corresponding kidney, on the other hand leads to increased functional activity of the opposite organ, which henceforth does the work of both. Obstruction of the ureter is most commonly due to the impaction of a calculus; and hence it is not altogether remarkable that a person who has had one ureter blocked up and one kidney destroyed should be liable to the occurrence, at some future time, of the same accident on the opposite side. And indeed it is generally in cases of this sort that mechanical suppression occurs.

*Symptoms and progress.*—The suppression of urine under these circumstances comes on suddenly. Sometimes it is, and remains, absolute; perhaps more frequently a small quantity of urine of low specific gravity, and containing little urea, is still passed at irregular and probably long intervals. It is very remarkable that in most cases of this kind, no matter how complete the suppression may be, the patient scarcely seems to suffer during the first seven or eight days. He may perhaps have a little nausea, there may be some degree of insomnia, and there may also be some failure of muscular strength; and this is all. At the end of this time, however, manifest symptoms of the effects of the retained poisonous matters on the system arise. They consist in the first instance in muscular tremors associated with distinct increase of muscular debility; and in the next place in slow, panting respiration, and contraction of the pupils. These phenomena appear never to be absent; and they become more and more marked with the progress of the case. But soon other symptoms are superadded. The patient complains of anorexia and thirst with dryness of the mouth and fauces; he becomes drowsy, but sleeps only in snatches; and he may present a little occasional delirium. Death, which is rarely preceded by coma, and still more rarely by convulsions, takes place mainly by asthenia at the end of two or three days from the first occurrence of toxæmic symptoms. Throughout the patient's illness there is no fever; on the contrary, towards the close the temperature tends to fall, the pulse differs little in frequency from the normal, and the skin is often moist. The symptoms, indeed, are in many respects widely different from those ordinarily attributed to uræmia.

The diagnosis of cases of this kind is often facilitated by the combination of a history of some long antecedent attack of renal colic on one side, with present symptoms of an acute attack of the same kind on the opposite side. The calculus soon, however, becomes impacted, and then probably all local pain and uneasiness disappear. Further, there is no necessary pain or uneasiness in the loin.

*Treatment.*—For this affection we can do little or nothing. We may adopt such treatment as is recommended for renal colic, in the hope that the stone, if there be one, may be aided in reaching the bladder; and we may endeavour, as Sir W. Roberts recommends, by kneading the abdomen, to empty the distended ureter and coincidentally, it may be, to dislodge the calculus. The feasibility of surgical interference might be worth consideration.

---

## SECTION II.—DISEASES OF THE PELVIC ORGANS

The diseases of the genito-urinary organs, situated within the pelvis, are of extreme interest and importance; but they are claimed for so many departments of practice that it is difficult to determine to what extent they ought to be included in a work on medicine. We propose to discuss very

briefly, and mainly in reference to diagnosis, those among them which are important on account of their liability to be confounded with or to complicate the diseases, already considered, of the other abdominal viscera.

## I. DISEASES OF THE URINARY BLADDER

1. *Inflammation* arises under many different circumstances, which need not be enumerated. It is characterised anatomically by congestion and thickening of the mucous membrane, with the secretion of mucus, which may be simply abundant or may acquire the character of pus. Sometimes submucous extravasations of blood occur, sometimes blood escapes from the surface. Occasionally ulceration takes place, or membranous pellicles form, or the mucous membrane itself or large patches of it exfoliate and are discharged. Occasionally, also, abscesses are developed in the substance of the vesical walls, or inflammation, commencing at the mucous surface, extends in depth until it involves the serous membrane.

The *symptoms* of inflammation of the bladder are mainly: pain and tenderness in the neighbourhood of the organ, therefore in the perinæum and immediately above the pubes, extending probably to the penis, to the sacrum or loins, and to the contiguous parts of the thighs; irritability of bladder, with constant desire to pass water; and the discharge of urine which, according to circumstances, presents only a slight cloud of mucus, or more or less abundant thick ropy mucus, or mucus mingled with blood or pus. Sometimes the urine contains shreds of tissue, and frequently becomes alkaline and offensive. Cystitis may be acute or chronic, and varies greatly in its intensity and danger in different cases. When acute the general febrile symptoms may be very severe. Cystitis often leads to pyelitis; and further, the latter affection not only resembles cystitis in some of its symptoms, but inflammation, commencing in the pelvis of the kidney, is apt to travel along the ureter and thus to involve the bladder.

For the *treatment* of cystitis we must refer to surgical works and to what has been previously said in reference to pyelitis.

2. *Tubercle* affects the bladder but rarely, and is then almost invariably associated with tubercle of the kidneys and ureters, or (which is yet more common) with tubercle of the prostate and vesiculæ seminales. It is of the miliary variety, and tends, as in the intestines and on other mucous surfaces, to produce shallow circular ulcers, which, by coalescence, are apt to cause superficial destruction of some extent. In a case under our own care, in which tubercle of the bladder was secondary to that of the kidney, the vesical mucous membrane was covered with raised, pale, circular, un-ulcerated patches about half an inch in diameter, which looked, except for their colour, much like an eruption of erythema circinatum.

The *symptoms* are in themselves undistinguishable from those of chronic cystitis.

3. *Morbid growths*.—The most important of these are villous tumours:

and the several forms of malignant disease. The latter usually commence in the prostate or some neighbouring part, and are rarely of primary origin in the bladder. Tumours are generally attended with pain referrible to the bladder, and more or less interference with micturition. Moreover, they are apt to be complicated, after a while, with symptoms of cystitis. Villous and malignant tumours are frequent sources of profuse hemorrhage. The latter are further characterised by sooner or later involving contiguous organs, and by inducing progressive cachexia.

4. *Dilatation*.—This depends on the accumulation of urine or other matters within the cavity of the bladder. It may occur in paraplegia and other paralytic affections from paralysis of the vesical walls, and also in hysteria. It is common in the later stages of many of the specific fevers, and during the typhoid condition, from failure of the reflex influence on which the evacuation of the bladder depends; and it is especially common as a consequence of obstructive disease, such as stricture of the urethra enlarged prostate, or tumours of any kind involving or compressing the neck of the bladder. When the dilatation is chronic, and secondary to some impediment, the muscular walls become hypertrophied and sacculi are developed. Under any circumstances the mucous surface is apt after a time to get inflamed; and the dilatation and inflammation are both of them liable, sooner or later, to involve the ureters and the cavities of the kidneys.

*Symptoms*.—In cases in which retention of urine is dependent on paralysis, or connected with the presence of febrile disturbance or the typhoid state, the bladder may become enormously distended without causing any apparent suffering to the patient. Even in cases of chronic stricture and such-like conditions in which, although the dilatation of the bladder may be extreme, it has been slowly attained, the organ becomes remarkably tolerant of its burden, and the patient suffers comparatively little. In other cases his sufferings are often extreme. He complains of general uneasiness, pain and tenderness over the hypogastric region, in the penis and in adjoining parts; but the pain is subject to frequent exacerbations, dependent on the violent but futile spasmodic efforts of the bladder to void its contents. In many cases, if the obstruction be not complete, more or less urine either constantly dribbles away or is passed in small quantities during the spasmodic efforts. The distended bladder forms a tense, ovoid tumour, which rises out of the pelvis from behind the pubes, and may extend upwards to the umbilicus or beyond. It occupies the middle part of the abdomen, and, unless it be largely sacculated, is symmetrical in form and position. The enlarged bladder can rarely fail of recognition if due attention be paid to the position and form of the tumour, to the perfect fulness on percussion which it presents, and to the characteristic pain which so often attends it and is evoked by manipulation.

*Treatment*.—When the bladder becomes distended in the course of fever and paralytic affections, equally as when it becomes distended in consequence of surgical diseases, the urine should be drawn off; and, if necessary, should be drawn off periodically. Further, if the urine be

ammoniacal, or there be discharge of ropy mucus or pus, it may be well not only to empty the bladder, but to wash it out either with pure water or with dilute antiseptic solutions. If a catheter cannot be introduced a surgical operation will of course be needed.

5. *Cyst of Müller's duct.*—In two cases which have come under our observation, a persistent Müllerian duct, opening by a comparatively large orifice in the situation of the sinus pocularis, formed an elongated cyst running upwards towards one of the kidneys. In one of them the cyst, which was convoluted and sacculated, measured about fifteen inches in length and in places between four and five in circumference, and was large enough to have been recognised during life.

## II. DISEASES OF THE UTERUS, FALLOPIAN TUBES, AND OVARIES

### A. *Metritis and Oophoritis*

*Causation and morbid anatomy.*—Inflammation of the parts above named may result from many causes, but is most apt to occur during the menstrual period and after parturition. Inflammation may affect the mucous surface only of the uterus, or this together with the muscular coat; and in the latter case is apt to spread to the surrounding connective tissue and to the peritoneum; the Fallopian tubes are frequently involved. The inflamed mucous membrane gets congested, thickened and pulpy, and occasionally (especially in the puerperal variety) is thrown off as a slough. The surface may at first be dry, but soon secretes a thin fluid, and subsequently pus, with which blood may be mingled. When the muscular parietes are involved, they become soft, tumid, infiltrated with inflammatory products, and occasionally studded with spots of extravasation. Sometimes abscesses form. Inflammation of the ovary, which is said to be most common on the right side, is characterised by swelling, cedema, and congestion of the organ, and occasionally goes on to suppuration. Its peritoneal surface is often involved, and adhesions are then apt to form between it and neighbouring parts.

*Symptoms.*—Metritis is generally a trivial ailment, attended with slight febrile symptoms; but it is sometimes, and more especially in puerperal cases, a disease of extreme gravity, rapidly ending fatally with symptoms which bear a close resemblance to those of pyæmia or severe erysipelas, with the former of which, indeed, it is apt to be complicated. The local indications of metritis are weight, pain, and tenderness in the situation of the womb. Pain and tenderness are felt in the hypogastric region, and occasionally a manifest tumour may be recognised in that situation. Uneasiness, pain, and soreness are referred to the sacrum or lower lumbar region, to the vulva and perinæum, and to the groins and inner aspects of the thighs. Further, tenesmus and painful or difficult micturition are often complained of. When the ovary is inflamed, the pain and tenderness

are referred to the region which the ovary normally occupies, namely, the point of intersection of the horizontal line drawn between the anterior superior spines of the ilia and the vertical line which divides the median from the lateral regions of the abdomen. The organ lies much higher than is generally supposed, and is deeply situated. When swollen it may often be distinctly felt in this situation.

### B. Morbid Growths

1. *Tubercle* is apt to affect the uterus and Fallopian tubes; it commences at the mucous surface and leads to the gradual destruction of the subjacent tissues, and to the abundant accumulation of cheesy matter. Much more rarely tubercle is discovered in the ovaries. Tubercle of these organs is almost always associated with advanced tuberculosis of other parts, more especially of the peritoneum.

The *symptoms*, if any special to these organs be complained of, are those of subacute inflammation.

2. *Myomata* are common in the uterus. They probably never occur before puberty; and affect virgins, it is said, more frequently than married women. They originate in the substance of the uterine walls; if near the inner surface tending to form polypi, if near the outer aspect to form pedunculated outgrowths into the cavity of the peritoneum, if in the more central parts to remain imbedded. They vary in size from mere points up to masses of many pounds' weight, and may be single or multiple. They are usually slow of growth, not unfrequently become stationary, and are liable after a time to undergo degenerative changes and to shrink. Similar tumours are occasionally developed in the ovary.

*Symptoms.*—In addition to the special symptoms due to their weight, to their pressure on neighbouring organs, such as the rectum and bladder, to their interference with parturition, and to their influence over the uterine functions, myomata frequently form masses which rise into the cavity of the abdomen, and may be recognised through the parietes as hard, rounded, or nodulated tumours. Such tumours necessarily vary in size, form, and position, and are generally unsymmetrical. Independently of vaginal examination, their situation in the neighbourhood of the uterus, their shape and density, their slow growth, the circumstances under which they have arisen, and the absence of involvement of lymphatic glands and remote organs, and generally of progressive cachexia, will usually enable an accurate diagnosis to be made. It must not be forgotten, however, that pedunculated tumours of this kind are apt to become attached to other parts, and, especially after pregnancy, to be left in comparatively remote situations, and thus to simulate renal or hepatic tumours, or tumours of other organs.

3. *Malignant disease* is liable to affect all the organs under consideration. The uterus is a frequent seat of its primary development; but this organ may also be affected secondarily. As a primary disease it usually commences between the ages of thirty-five and fifty; and generally takes its origin in the cervix or os. Carcinoma is probably its most common form,

but epithelioma and sarcoma are neither of them rare. The ovaries, also, are not very unfrequently the seat of cancerous or sarcomatous growths. These may be primary in them or secondary to growths elsewhere. They are generally associated with similar disease in either the uterus, the peritoneum, or other abdominal organs. Ovarian malignant disease results for the most part in the development of lobulated masses, which in their general outlines are not unlike ovarian cystic tumours; and, indeed, it is common for malignant disease of the ovaries to be associated with the development of cysts.

The *symptoms* of malignant disease of the uterus need not detain us. And with respect to those of malignant disease of the ovaries, it may be observed that the tumours would probably in themselves be undistinguishable from ordinary ovarian tumours, and that their recognition as being dependent on malignant disease must rest upon the progress of the case, the development of tumours elsewhere, the early appearance of cachexia, and the rapid downward tendency of the case.

### C. Cystic Tumours

*Causation and morbid anatomy.*—Cysts may arise either in the uterus, Fallopian tubes, or ovaries, or in connection with the peritoneal aspect of these organs or their ligaments.

1. *Dilatation of the uterus* may be caused by accumulation of menstrual fluid, owing either to obstruction at the os uteri or to imperforate hymen or vagina. This is an affection of early life. At a later period, owing to obliteration of the os, or to its obstruction by tumours or other causes, the uterus may become distended by the glairy secretion of its mucous surface. Under the latter circumstances the uterus rarely attains a greater size than the fist; under the former it may slowly acquire the bulk of the gravid organ, or even surpass it. The uterus may also be distended with blood.

2. The *Fallopian tube* occasionally undergoes dilatation. This condition is secondary to its closure or obstruction, generally at or near its junction with the uterus. The affected tube becomes elongated, tortuous, and sacculated, and increasingly dilated towards its fimbriated extremity. Here it occasionally measures three or four inches in diameter.

3. *Parovarian cysts* are occasionally developed in the fold of peritoneum lying between the ovary and Fallopian tube. They commonly remain of small size, and of no practical importance. They are apt, however, to attain large dimensions, and then, like an ovarian cyst, to occupy the whole of the front of the abdomen from the ensiform cartilage down to the pubes. They are usually unilocular, thin-walled, and filled with a limpid watery fluid, of very low specific gravity, containing little or no albumen, and presenting a considerable quantity of common salt. Their contents hence closely resemble those of hydatid cysts, for which in fact they may be mistaken. Moreover, they are occasionally somewhat flaccid, and on percussion yield a prolonged thrill not unlike the hydatid fremitus. Their situation corresponds to that of ovarian cysts. They

are distinguishable from these, however, partly by the nature of their contents, partly by the fact that they are often cured permanently by a single tapping.

4. *Ovarian cysts*.—But by far the most common and important cystic tumours are those which arise in the substance of the ovary. These may be simple or compound; may vary in size from that of a marble up to a bulk far beyond that of the pregnant uterus; and may form either a uniformly rounded or ovoid mass, or an irregular lobulated tumour. They may be limited to one ovary, or, as not unfrequently happens, may affect both organs in unequal degrees.

Cystic tumours of the ovary are rare before puberty. But from twenty or twenty-five upwards they are not unfrequent. They are most commonly met with between the ages of thirty and forty. The disease commences with the development of one or more small cysts in the substance of the ovary. These gradually increase in size; and as they grow other cysts arise in relation with them, either in the ovary itself, or, if all manifest ovarian structure have disappeared, in the substance of the cyst-walls—a process which tends to go on indefinitely as well in the walls of the secondary and all other later generations of cysts, as in those of the primary cysts. The result is the development of a more or less complicated cystic mass the characters of which differ according to a variety of circumstances.

In some cases the secondary cysts tend largely to grow from the outer surface of the primary cysts, and hence the tumour soon acquires a marked lobulated character; in some cases they appear mainly in the thickness of the party-walls between adjoining cysts, and the tumour becomes multilocular, and presents a good deal of resemblance in its structure to an accumulation of air-bubbles in a viscid fluid; in other cases the new growths are developed chiefly in connection with the inner surface of the cysts, and project or grow into their interior. The last mode of development presents several varieties; in some instances papillæ, villi or pedunculated cysts spring in groups from the lining membrane; in some instances, and on the whole more frequently, these intra-cystic growths resemble those from which they spring, themselves give origin to others, and thus tend gradually to fill and even to distend the cavity which they occupy.

The proportionate development of the constituent cysts presents great differences. In some instances one cyst becomes so large relatively to the others that the tumour becomes practically unilocular. In others the cysts are so numerous and small that the tumour appears to be nearly solid. And between these extremes all varieties may be met with. The enlargement of the tumours is due not solely to the formation of new cysts, but in great measure to the dilatation of the cavities already in existence. This is effected partly by the stretching of their parietes by their accumulating contents, and partly by the yielding of their parietes at points and the consequent coalescence of neighbouring cysts—a process which may be readily observed in all its stages in most ovarian tumours.

The contents of ovarian cysts differ largely. In many cases they are colourless; but they are often yellow, brown, or green. They may be

transparent as water, or opaline, or perfectly opaque. They may be limpid, but are more usually glairy or viscid, and not unfrequently are thick, and glue- or jelly-like. When thick they often present a whitish or brownish sediment. Chemically they contain modified albumen, and either mucus or colloid matter, and sometimes altered blood. Corpuscles of various kinds, more or less degenerated, are generally present; sometimes pus. Cholesterine is often observed.

The walls of ovarian tumours vary greatly in thickness. Sometimes they are as thin as tissue-paper and perfectly pellucid. Much more frequently they are thick and tough, though varying in thickness in different parts. The outer parietes, like the party-walls between cysts, have in the progress of their growth a tendency to become attenuated and to give way at points. In thin-walled tumours free communications are occasionally thus established between the cysts and the abdominal cavity, which consequently becomes distended with their profuse secretion. And even in thick-walled cysts such communications, attended with escape of contents, are not unfrequent. The walls of ovarian tumours consist mainly of connective tissue, in which are not unfrequently found microscopic cysts, together with patches or masses of cell-growth having some resemblance to sarcomatous or adenoid tissue.

Among the various consequences of ovarian cystic tumours may be enumerated: the occurrence of inflammation or suppuration; rupture of the cysts with the discharge of their contents into the peritoneal cavity; the communication of suppurating cysts with the rectum, bladder, or other neighbouring hollow viscera; the occurrence of peritonitis or ascites; and pressure on the bladder, rectum, ureters, or iliac veins, with the usual consequences of such pressure.

*Symptoms and progress.*—The uterus dilated by fluid contents takes the ordinary form, and occupies the usual situation, of the gravid organ; and, from these and other considerations, the nature of the lesion can always be pretty readily ascertained. For the diagnosis of these cases, however, and of those of dropsy of the Fallopian tubes, we must refer to works upon the special diseases of women.

Ovarian cystic tumours, in the early stage of their growth, either are unattended with symptoms, or produce discomfort by sinking into the pelvis and interfering by pressure with the functions of one or other of the neighbouring pelvic organs. At this period they are probably detectable through the abdominal parietes, or by vaginal examination. With the progress of their enlargement they rise into the abdominal cavity, and ultimately in some cases produce enormous distension, displacing the abdominal viscera, and even, by direct or indirect pressure on the diaphragm interfering with the respiratory functions. An ovarian tumour of moderate size can generally be recognised as ovarian: by its obvious connection with one or other of the iliac regions, whence probably it extends into the adjoining parts of the abdomen; by its irregularity of form and the various degrees of resistance of its several lobules, with the probable distinct fluctuation of some; by its dulness on percussion; by its displacement of

the intestines, and its mobility; and by the absence of pain, tenderness, cachexia, and secondary growths. When it has attained a large size, all evidence of its commencement at one side of the abdomen has probably disappeared. But there is usually even then distinct evidence of its development from the lower part of the abdomen in the fact that the intestines are displaced upwards and laterally; so that, in addition to tumour, there is complete dulness on percussion from the pubes upwards and outwards. The intestinal resonance can generally be distinguished in the flank, and that due to the stomach, transverse colon, and perhaps some of the small intestines above. The tumour in this case also is probably irregular as to both form and resistance; but it frequently happens that one or two cysts preponderate largely over the others, and that distinct fluctuation may be felt in them. In some instances the bulk of the tumour consists of a single cyst; and the tumour may then not only fluctuate distinctly but present a fairly uniform rounded shape. Pain, tenderness, and fever are not necessary accompaniments of ovarian tumours; but these phenomena and others may arise during the progress of the disease. They depend on the supervention of one or more of those complications which have been previously enumerated—namely, inflammation in the cysts or in the peritoneum which surrounds them, the development of ascites, or pressure on the pelvic organs. When the tumour becomes very large, the patient's gait resembles that of a pregnant woman; the legs get congested and anasarcaous; loss of appetite and perhaps vomiting supervene; and the breath becomes short. Ultimately progressive emaciation and asthenia come on.

Ovarian tumours are generally easy of diagnosis. They are apt sometimes to be confounded with uterine, hydatid, or other growths springing from the pelvis, and indeed cannot always be distinguished from them. When of large size and mainly mono-cystic they may be mistaken for ascitic accumulations. But the anterior position of the ovarian tumour; the existence of resonance above and in the flank and of dulness over the whole of the tumour; the tendency for the abdomen to be thick rather than wide, and to present some degree of irregularity of form; and the total absence of any change in the level of the line separating the dull from the resonant regions when the patient shifts her position, are usually sufficient to enable an accurate diagnosis to be made. But ascites is apt to come on in the course of ovarian dropsy, and hence the two conditions are not unfrequently associated.

*Treatment.*—The treatment of ovarian cystic tumours alone calls for remark here. And even in reference to this subject we have little to say. Drugs have no influence, direct or indirect, over them. Of course if inflammation arise, the treatment usually adopted for peritonitis may be had recourse to; if the patient be weak and emaciated, tonics and nutritious diet may be prescribed; if she be suffering materially from the bulk of the tumour and its pressure on the stomach, diaphragm, or other organs, it may be tapped. But the only efficacious treatment is by the knife. The success of ovariectomy, or removal of the ovarian tumour by opera-

tion, has been so great of recent years that all other forms of treatment have fallen into desuetude, excepting for those cases which from various circumstances are unsuitable for the radical cure.

---

### III. DISEASES OF THE PELVIC PERITONEUM AND CONNECTIVE TISSUE

We cannot conclude this section without directing attention to the remarkable tendency there is in the case of the pelvis, as there is also in that of the upper part of the chest, for diseases originating in one organ to implicate other organs in the vicinity, and for affections therefore originally distinct to cause almost identical ultimate results.

Inflammations commencing in the ovary, uterus, or vagina, in the rectum, cæcum, or bladder, in the serous membrane covering these organs, or in the connective tissue which invests them, or in connection with the bones or joints of the pelvis, are all apt to involve pelvic peritonitis, with adhesion, infiltration and induration of the connective tissue of the pelvis, and the formation of abscesses which may burrow in various directions and open into the bladder, vagina, or rectum, or superficially in the perinæum, above the pubes, in the groin, or in the buttock. Further, as has before been pointed out, abscesses may gravitate from any of the parts situated in the abdomen or chest along the retro-peritoneal tissue, and thus induce the same consequences in the pelvis as though they had originated there.

Similar remarks may be made in reference to the consequences of tubercular disease of the uterus and Fallopian tubes, of the prostate and vesiculæ seminales, and of the bladder, the clinical phenomena of which are mainly those of subacute inflammation of the same organs.

Malignant disease of whatever kind soon spreads by continuity from the part in which it originates, and implicates all organs in its vicinity. If it commence in the uterus or vagina, it speedily infiltrates the surrounding connective tissue, and then presently involves, on the one hand the bladder, on the other the rectum, leading to free communication between these several viscera. Similarly malignant disease, commencing in the rectum or anus, in the bladder, or parts at the neck of the bladder, or in the connective tissue investing these parts, or growing from the inner aspect of the pelvic bones, tends to the ultimate production of exactly similar results—to the formation, in fact, of a common excavation into which the several pelvic organs sooner or later discharge their contents. Communication between the vagina and the rectum or bladder leads to the discharge of fæces or of urine per vaginam. Communication between the bladder and rectum is likely to be attended, on the one hand, with the escape of fæces into the bladder, and the discharge of fæcal matter and of flatus from the urethra; and, on the other hand, with the passage of urine into the rectum.

In the above cases, but mainly in that of malignant disease, other consequences are liable to ensue, more especially, perhaps, implication of the peritoneum, the laying open of vessels with the occurrence of more or less abundant hemorrhage, and the involvement of nerves, particularly those of the sacral plexus, with the production of local pain and tenderness and of pain taking the course of the sciatic nerve and mistakable for sciatica, and apt to be followed by wasting of the muscles and cutaneous eruptions. Further, obstruction of the ureters with consequent hydro-nephrosis, retention of urine, impediment to the discharge of feces, tenesmus, irritability of the bladder, and œdema of the lower extremities or of the organs of generation, are all liable to occur in different cases at different periods in their progress.

## CHAP. VII.—DISEASES OF THE ORGANS OF LOCOMOTION

### I. RHEUMATISM (*Rheumatic Fever*)

*Definition.*—The term rheumatism is often applied to all inflammatory or painful affections of the fibrous and muscular tissues which are not clearly referrible to injury, gout, pyæmia, or any other well-recognised specific disease. With more precision it is used of inflammatory affections of the joints and other fibrous tissues which, depending apparently on some general or constitutional morbid state, have a tendency to migrate, or spread, as it were, by a kind of metastasis.

*Causation.*—The essential causes of rheumatism appear to be the same as those of pneumonia, and many other varieties of idiopathic inflammation—namely, exposure to cold and wet, sudden chills, and long-continued exposure to any cooling influence which exercise or clothing fails to counteract. Getting wet through, and even having the feet damp and cold for any length of time, are common examples of the methods by which these agencies act. It must be allowed, however, that there are many predisposing causes which exert an important influence over the production of rheumatism. If we may accept the results of statistical inquiries, it seems clearly proved that the children of rheumatic parents are on the whole more liable to suffer than those who come of a non-rheumatic stock. Age certainly has some influence, for young infants seldom if ever are attacked with rheumatism, and the old, when they suffer, suffer mainly from its chronic forms, or from its sequelæ. It is probably most common as an acute disease between the ages of ten and thirty. Sex has little influence, for, although males on the whole are oftener affected than females, the difference is probably entirely referrible to the influence of their respective avocations. The most important of the predisposing causes are: first, the fact of having previously had an attack of rheumatism; and second, the condition of the patient's health at the time of exposure. It is well known that those who are suffering from scarlet fever, those who have gonorrhœa, and women immediately after childbirth, are peculiarly liable to be attacked with rheumatism, which then often becomes modified in character. Further, inasmuch as rheumatism depends essentially on vicissitudes of temperature, and other allied conditions, it is of specially common occurrence in cold, damp, and more particularly variable climates, and during those seasons of the year in which these conditions prevail.

*Morbid anatomy.*—With one or two remarkable exceptions, to be

presently adverted to, the morbid anatomy of rheumatism calls for little comment. The affected joints present hyperæmia of the synovial fringes and of the parietal layer of the synovial membrane, with excessive effusion of synovial fluid into their cavities and exudation of serum into the soft tissues around. The former fluid may either still present the ordinary characters of synovia, or be turbid, milky, or flocculent. On microscopic examination, the epithelial cells of the synovial surface will be found swollen and plump, more or less fatty, and in some cases converted into granule cells; and similar organisms, together with cells of pus or mucus, will be recognised in the synovial fluid. Changes also go on (according to Cornil and Ranvier) in the articular cartilages. These depend mainly on nutritive irritation of the cartilage cells, which swell up, assume a globular form, and according to the usual routine (commencing with division of the nuclei) become filled with secondary cells, which speedily acquire special secondary capsules. This condition does not involve the whole extent of cartilage, but occurs in scattered spots which, when they implicate the surface, reveal themselves to the naked eye by their prominence and comparative softness. Striation of the hyaline matter of the cartilage frequently attends this process; and as this is mainly vertical in its direction, the cartilage may sooner or later acquire a velvety character. Rheumatic inflammation rarely results either in suppuration or in permanent disorganisation of the parts affected. Sometimes, however, a joint suppurates; sometimes ulceration of the cartilages takes place; and sometimes the tissues external to the cavity become infiltrated with inflammatory lymph, matted together, and indurated. Drs. T. Barlow and Warner have called attention to the development, in the course of rheumatism, of subcutaneous fibrous nodules, varying for the most part between the size of a pin's head and that of an almond, but occasionally reaching larger dimensions, which occur chiefly in the neighbourhood of joints, especially about the back of the elbows, the margins of the patellæ, and the malleoli, but may be looked for also in relation with the vertebral spines, the iliac crests, the clavicles, the extensor tendons of the feet and hands, the ears, the temporal ridges, the superior curved line of the occiput, and the forehead. The skin is generally freely movable over them, and they are slightly movable over the fibrous textures upon which they lie. They are chiefly met with in young children. Dr. Barlow, who observes that they are generally associated with heart disease, is inclined to think that they are of the same character as the inflammatory exudations which form the basis of valvular disease. The effects of rheumatic inflammation, discoverable post mortem in most other fibrous tissues liable to be affected, are trivial, and need no special consideration.

The lesions of exceptional importance to which reference has been made are rheumatic affections of the heart and pericardium, and similar affections more rarely involving the lungs and pleuræ. These are more particularly pericarditis, endocarditis, pleurisy, and pneumonia, which are all fully discussed elsewhere under their respective names. In acute rheumatism the blood always contains a large excess of fibrine, and it is

common after death to find large fibrinous coagula in the cavities of the heart and large vessels.

*Symptoms and progress.*—The symptoms of rheumatism are liable to great variety; and especially they are liable to vary according as the rheumatism is confined to certain organs or tissues, or becomes a more general disorder. The differences, indeed, between these two forms of the disease are so great that many regard them as entirely distinct affections.

The first form is generally traceable to the direct exposure to cold or wet of the part which becomes affected; it is often chronic in its course and intractable, yet by no means necessarily attended with indications of constitutional disorder. Sometimes it affects the fibrous structures of the soles of the feet; sometimes the muscles of the lumbar region (*lumbago*); sometimes the great sciatic nerve (*sciatica*); sometimes the intercostal muscles; sometimes the muscles of the neck or shoulder, and especially, perhaps, the sterno-mastoid (*stiff neck, torticollis*); in all of which cases the local symptoms generally suffice for the identification both of the part affected and of the nature of the disorder.

The more general and acute form of rheumatism, or *rheumatic fever*, as it is often called, sometimes comes on without warning, with elevation of temperature, alternate heats and chills, possibly rigors, and other usual indications of high fever, upon which, in a few hours, or perhaps a day or two, the characteristic local phenomena supervene. Sometimes, on the other hand, the acute symptoms of the general disorder suddenly follow upon slight rheumatic pains which have been for some time flying about the limbs, or have been limited to some muscle, or fibrous expansion, or joint, or in the course of one of those varieties of localised rheumatism which have already been enumerated. But however the acute attack begins, its symptoms (apart from differences due to variations in severity and the occurrence of complications) present a great and striking simplicity.

The parts which usually and chiefly suffer are the larger joints, especially the wrists, elbows, ankles, and knees; but no joint enjoys immunity; and thus not only the hip and shoulder joints, and those of the spinal column, but those also of the clavicle, and those even of the carpus and tarsus, fingers and toes are all liable to be affected in the course of an attack. Further, the muscles of the limbs and other parts of the body by no means unfrequently suffer. The affected joints become very painful and tender, so that the patient dares not move them, and cannot bear that they be moved for him or touched, or even that his bed be shaken. They usually also swell, partly from effusion into the synovial cavity, partly from inflammatory infiltration of the surrounding tissues. This swelling is always most manifest in connection with those joints which are least thickly covered, especially, therefore, those of the hands and feet, and the wrists, elbows, ankles, and knees. It is mainly in these same joints, and along the course of the sheaths of the tendons in relation with them, that superficial inflammatory congestion, which is often absent, is seen. Rheumatic inflammation is generally characterised, not only by its tendency to attack joints successively, but by its relatively short duration in

any one joint. Thus, for the most part, each joint which is implicated becomes painful, swollen, perhaps obviously congested, and recovers its normal condition, all in the course of a few days, or even a few hours ; and as a rule neither pitting nor desquamation ensues. And thus, again, we often find that only one or two joints are acutely affected at a time ; or that, if the patient complains of general implication of the joints, some present the earliest indications of inflammation, and others have attained their highest point, whilst most are in various stages of convalescence. There is nothing protective in one attack of inflammation of a joint against subsequent attacks in the same joint ; and hence the implication of any one of these organs may be repeated indefinitely in the course of the same attack of rheumatism.

The other symptoms of the disease are in some respects almost as characteristic as the joint affection itself. The temperature is sometimes elevated only by a degree or two, rarely rises above  $105^{\circ}$ , and generally falls short of this maximum by one or two degrees. It is liable to diurnal variations, which, although there is commonly a morning remission and an evening exacerbation, are on the whole irregular and untypical. Rigors are sometimes present. The skin almost always yields excessively copious sweats, which (although not actually more acid than healthy perspiration) are attended with a peculiar and almost pathognomonic sour smell. These, by their profuseness and long continuance, generally induce an eruption of sudamina, which are often seated on congested bases, and then apt to be mistaken for eczema. The pulse is quickened, but not generally in adults to beyond 100 or 110 ; it is regular, and as a rule full and bounding. The respirations are somewhat accelerated ; the tongue is for the most part thickly coated with a moist creamy fur, and occasionally becomes dry, brown, and fissured. There is failure of appetite with excessive thirst. The bowels are usually constipated. The urine is scanty, of high specific gravity, high-coloured and acid ; contains abundant urates, which, with crystals of uric acid, commonly deposit on cooling ; and presents an excess of urea and extractives, with a deficiency of chlorides. The patient is restless, often pallid, wears an aspect of weariness, anxiety, or pain, but rarely presents delirium or other forms of mental disturbance.

There is no definite limit to the duration of acute rheumatism. Sometimes the patient recovers completely in the course of a day or two, or of a week ; more commonly the disease persists for several weeks ; and not unfrequently it becomes chronic, or is continued by successive relapses for a much longer period. It is generally observed that those cases in which the small joints are specially affected are of longer duration than those in which the larger joints mainly suffer. And, further, the febrile symptoms often subside, while certain of the joints pass into a chronic condition of disease. Sometimes, owing to relaxation of the ligaments, certain joints remain weak for an almost indefinite time ; sometimes they continue stiff, swollen, and tender ; sometimes dislocation takes place, or the opposed surfaces cohere, or the soft tissues around get matted together with chronic

inflammatory infiltration, and the joints consequently become fixed or otherwise permanently impaired. Suppuration seldom occurs.

The complications of rheumatism are numerous and important. It may, however, be a question whether some of the so-called complications should not be regarded as integral parts of the disease equally with the inflammation of the joints. Rheumatism is characterised essentially by inflammation of the fibrous structures; for the most part (as has been pointed out) it is those of the joints which suffer, but those connected with muscles, nerves, and fasciæ are also liable to be involved. But of all, excepting those of the joints, the fibrous structures of the heart are most frequently implicated; and, indeed, the heart in this respect might be regarded as one of the joints, for it is at least quite as liable to suffer as any one of them. In a large proportion of cases of acute rheumatism, especially in young persons, the heart becomes involved in the course of the disease; occasionally the heart affection precedes that of the joints, and it may even be the only local rheumatic manifestation. The exact numerical relation between heart disease and rheumatism is very difficult to determine; partly because slight attacks of pericardial inflammation and the scanty formation of warty masses on the auricular aspect of the mitral valve may very readily escape detection during life; partly because, when once an attack of rheumatism has occurred with distinct cardiac complication, it is often impossible to be certain whether or not in subsequent attacks further cardiac mischief has accrued. The endocardium suffers more commonly than the pericardium. The symptoms and consequences of the various cardiac lesions are all fully discussed elsewhere; we may, however, point out that the supervention of cardiac complication is often attended with such slightly pronounced symptoms that it may either pass unnoticed or only be discovered on casual physical examination, while, on the other hand, its symptoms are sometimes so grave and dangerous that they entirely overshadow those of the general rheumatic attack. It need scarcely be said that, in every case of rheumatism, no matter how slight it is, the condition of the heart should be carefully watched. Pleurisy, pneumonia, and bronchitis, again, are not uncommon complications of acute rheumatism; of these, pleurisy is probably the most characteristic. Peritonitis, too, occasionally supervenes; as also do jaundice and inflammation of the iris and sclerotic. The subcutaneous fibrous nodules, which are occasionally observed, are seldom the seat of tenderness or pain; they vary as to number and distribution, rarely last more than a few weeks each, and often appear successively or in crops. Skin eruptions are very apt to occur in the course of rheumatism. Reference has already been made to the frequent presence of sudamina; other eruptions are mainly varieties of erythema or roseola, and especially of those varieties included by Hebra under the generic term of erythema multiforme. They are (to give them their specific names), *e. papulatum*, *e. circinatum*, *e. marginatum*, and, besides these, *e. nodosum*, and, according to Trousseau, *erysipelas*.

It has already been pointed out that uncomplicated rheumatism, how-

ever severe it may be, is rarely attended with cerebral disturbance; nevertheless it occasionally happens that symptoms referrible to the central nervous organs break out with the suddenness that characterises the onset of cardiac mischief, or that of each attack of joint inflammation. The occasional severity and fatal character of these nervous complications has not unnaturally led to the belief that the membranes of the brain or cord have become implicated in the same way as other fibrous structures; and it is not improbable that in some cases this actually takes place. It must be acknowledged, however, that post-mortem examination rarely gives evidence of such implication. In some cases (especially if there be recent heart disease or pulmonary complication) the patient may have that kind of delirium which so often attends pneumonia and various specific febrile diseases—a delirium mostly occurring between sleeping and waking, and from which he can be easily roused. In some cases the patient has (more or less gradually developed) some form of mental alienation; while quiet in manner he gets suspicious and sly, taciturn and morose, has hallucinations, hears voices, sees visions, believes that he shall be poisoned or murdered or that the police are on his track, and may at any moment become violently maniacal. In some cases he becomes hemiplegic, paraplegic, or choreic, or even suffers from tetanic spasms, with lockjaw and risus sardonicus. From all such conditions he not uncommonly recovers completely, but sometimes they are the precursors of coma terminating in death. Fatal coma is ushered in variously: with lowness of spirits, insanity, delirium or typhomania, giddiness, headache, singing in the ears, affection of the sight, paralysis, or convulsions. Sometimes it comes on suddenly with an apoplectic seizure; and death may ensue in from twelve to twenty-four hours, or even in four or five hours from the first appearance of the nervous symptoms. It has been observed that in some of these cases there is during the attack either an excessive flow of limpid urine, looseness of bowels, or both of these conditions.

Although, as a rule, the temperature in rheumatism does not exceed  $105^{\circ}$ , it occasionally rises with great rapidity to  $107^{\circ}$ , or  $108^{\circ}$ , or even  $110^{\circ}$ ,  $111^{\circ}$ , or  $112^{\circ}$ ; and such excessive rises are almost invariably of fatal augury. Hyperpyrexia often occurs in association with some of the complications which have been discussed, such as acute cardiac or pulmonary disease. But it often also comes on in uncomplicated cases, and unexpectedly. The symptoms vary. But for the most part, the perspirations cease and the skin becomes dry, the tongue gets dry and coated, the pulse and respirations increase in frequency, the patient is restless, perhaps presents slight convulsive movements, and even becomes delirious. But finally insensibility supervenes, and he dies comatose in the course of a few hours after the beginning of his attack. The cause of hyperpyrexia in rheumatism is obscure. Dr. H. Weber draws attention to the close resemblance subsisting between these cases and cases of sunstroke. The relations of rheumatism, through cardiac disease, with chorea and embolism are fully considered elsewhere.

It will be readily gathered from the foregoing account that indepen-

dently of all so-called complications, rheumatism is liable to present within certain limits many varieties of character. It may be acute, or it may assume a chronic form, and may, in fact, continue with relapses for months or years; it may attack chiefly the larger joints, or it may, as it were, select the smaller ones; instead of temporarily involving joint after joint in irregular succession it may spend its force on one or two and damage them irremediably; it may cause inflammation mainly of the synovial membranes with effusion into the synovial cavities in one case, mainly of the soft tissues around the joints with infiltration of these tissues in another, or mainly of the fibrous sheaths of muscles or nerves in a third; when developed in connection with gonorrhœa it is peculiarly apt to become intractable and to lead to permanent injury of the affected joints; when it arises after childbirth or in the course of some of the specific fevers, the inflammation it evokes may assume a suppurative character. Yet, however long the duration of rheumatism, or however severe or various it may be in its local manifestations, it is seldom dangerous to life, unless it be through the instrumentality of one or other of the more serious complications which have been discussed; but these are fatal in a high degree, sometimes immediately, more frequently at a later period of life, in consequence of the more or less slowly developed effects of the organic lesions of vital organs which they induce.

*Pathology.*—It remains to say a word or two in reference to the pathology of rheumatism. Is it a local disease, or is it a constitutional disease? Does it depend on the presence of some specific poison circulating in the blood, on the action of the blood-vessels, and the action of the vaso-motor nerves, or on what? These are questions of considerable difficulty, and impossible to discuss fully in the space at our disposal. It seems to us, however, that there is little or nothing in rheumatism, in respect of its proximate cause, to distinguish it from pneumonia, bronchitis, nephritis, erysipelas, or any other example of local inflammation caused by exposure to cold or cognate conditions. If these be constitutional diseases, so is rheumatism; if they be local diseases, rheumatism is also in the same sense a local disease—a disease, that is to say, involving a special tissue, but one which happens to be largely distributed throughout the system. That the blood becomes abnormal in rheumatism is certain, and especially is it certain that it contains an excessive quantity of fibrine and of the products of disintegration of tissue; but these are the mere consequences of the rheumatic process, and have no more to do with the production of rheumatism than the similar condition of the blood in pneumonia has to do with the production of pneumonia. The proximate cause of rheumatism has been largely held to be a poisonous substance circulating in the blood, and the copious perspirations have been regarded as an effort of nature for the elimination of this poison; it has even been maintained that the poison is either lactic or some other acid. No excess, however, of any such acid has yet been detected in the blood or perspiration of rheumatic patients; and if there be a rheumatic poison, which is possible, its discovery is in the future.

*Treatment.*—Innumerable remedies have been vaunted for the cure of rheumatism, yet it remains one of the most unmanageable complaints which physicians can be called upon to treat. Some advocate the use of iodide or bromide of potassium in frequent medium doses; some that of nitrate of potash in daily quantities varying between 1 and 3 ozs. largely diluted and taken as a drink; some that of alkalies, and more especially of the bicarbonate of potash in doses of from 20 to 30 grains given every hour or two; some recommend colchicum, some veratria, some guaiacum, some quinine, and some opium, in quantities sufficiently large and sufficiently frequently repeated to induce their respective specific actions. Dr. Garrod prefers a combination of quinine and bicarbonate of potash in about 5 and 30 grain doses respectively. Others trust mainly to local treatment: simple hot fomentations, hot fomentations with which alkalies and laudanum have been mixed, counter-irritation by means of spirit or turpentine, mustard plasters or blisters. Blisters especially have been brought into prominent notice by Dr. Herbert Davies. Others, again, trust to 'packing,' or to vapour, hot-air, or hot-water baths.

By far the most valuable and efficacious treatment of acute rheumatism is that by salicylic acid or salicylate of soda. This, if given in sufficiently large and frequently repeated doses, has a marvellous power of reducing fever, and at the same time of relieving and cutting short the local inflammations and the pain attending them. Of the above preparations the salicylate is the most convenient and the best; but either may be given to an adult in 20 or 30 grain doses every two or three hours. The continuance of the drug must be determined by its effects. So soon as the temperature has fallen to the normal and pain has subsided, it must either be discontinued or be given in smaller or less frequent doses. It is necessary to watch the patient carefully during its administration, for various undesirable, if not dangerous, symptoms are liable to supervene and to compel the discontinuance or diminution of the medicine. Among these the more important are albuminuria, sickness, noises in the ears, deafness, and especially delirium.

As a general rule a rheumatic patient should be kept in a comfortably arranged bed, well covered with bed-clothes, and protected if necessary by mechanical means from their undue pressure; perspiration should be encouraged, and the inflamed joints covered with cotton-wool; pain should be relieved and rest obtained by the administration of opiates; thirst should be appeased and secretions promoted by the administration of abundant diluents, such as lemonade, soda-water, milk, beef-tea, and broths; and nutrition should be maintained by the use of such food (mostly fluid and farinaceous) as the patient can be persuaded in reason to take. He should be placed in a warm room, well ventilated, yet free from draughts, from which indeed he should be protected by curtains. In addition some one of the lines of medicinal treatment above indicated may be pursued, or counter-irritation may be practised. As regards the use of blisters, we may state that they do, according to our own experience, afford almost immediate and marvellous relief to the pain of the inflamed joints in the

neighbourhood of which they are placed, and that they may be applied to joint after joint in the progress of rheumatism without any ill-effect whatever, but that they do not cut short the progress of the inflammation which they relieve, and have no influence whatever over the general progress of the rheumatic attack. Colchicum is said to be specially efficacious when the rheumatism is attended with marked dropsy of the synovial cavities ; and iodide of potassium or guaiacum is considered to be chiefly beneficial in chronic cases. During convalescence from rheumatism, great care should be taken to avoid cold and draughts, and the patient should be warmly clothed in flannel. He should, moreover, be put on a course of quinine and iron or some other tonic, well fed, and if necessary removed for a time at least to some more genial neighbourhood.

When rheumatism becomes chronic, or rheumatic pains are a source of trouble from time to time, or the patient suffers from rheumatism of certain fasciæ, muscles, or nerves, various measures are open for us to adopt for his relief. Hot-air baths, vapour baths, hot-water baths, Turkish baths frequently repeated, are often exceedingly valuable. Counter-irritation, especially by means of blisters or stimulating liniments, hot fomentations, the application of belladonna or aconitia, or even the removal of blood by leeches, may be of more or less benefit. Opiates, especially given by subcutaneous injection, are often of marvellous efficacy. For general treatment, we may have recourse to the drugs supposed to be serviceable in the acute form of the disease ; but those most likely to be of use now are probably iodide of potassium, guaiacum, quinine, iron, and other tonics.

For the treatment of the complications of rheumatism we must refer the reader to the articles in which these affections are specially considered. We may, however, observe that when cerebral or spinal symptoms manifest themselves, it is generally advisable to act freely on the bowels, to employ revulsive treatment, and to place our trust (as regards internal remedies) in opium and diffusible stimulants. If hyperpyrexia come on (if the temperature rise above  $105^{\circ}$  or  $106^{\circ}$ ) it may be advisable to reduce it by the application of external cold. This may be done either by sponging the patient's body with tepid or cold water, or by surrounding him with sheets kept moist and cool by pouring water over them from time to time, or, best of all, by placing him in a bath, the temperature of which may at the beginning stand at about  $98^{\circ}$ , but which is allowed to cool gradually to  $60^{\circ}$  or  $70^{\circ}$ . The patient may be subjected to such treatment for half an hour or even an hour at a time ; but the propriety of continuing or determining it must be judged of by his condition. It should not be continued after he begins to shiver or look cold, or after his temperature has been reduced to the normal. But if the temperature rises it may need to be repeated frequently and at short intervals. There is no doubt that patients are often saved from death by this treatment. Antipyrrin, antifebrin, and other medicines which reduce bodily temperature in febrile disorders, appear to have little or no influence over the above and other cases of hyperpyrexia.

II. RHEUMATOID ARTHRITIS (*Chronic Rheumatic Arthritis*)

*Definition.*—This affection, which consists essentially in a chronic irritative outgrowth of the cartilages and synovial fringes of the joints, associated with progressive destruction of those parts of the cartilages which are most subjected to pressure, has been described under various names, among which may be mentioned ‘chronic rheumatism,’ ‘chronic rheumatic arthritis,’ ‘nodular rheumatism,’ and ‘arthritis deformans.’

*Causation.*—It occurs far more frequently in women than men; and comes on in them mostly, it is said, about the period when menstruation ceases. It may, however, commence at any time of life, and has been recognised even in young infants. Its cause is obscure. But it is certain: that many of those who suffer from it have had acute rheumatism of the ordinary type at some earlier period of life; that in some cases its commencement may be clearly traced to those conditions which are productive of acute inflammation; and that most of those who suffer from it are highly sensitive to vicissitudes of temperature and changes of season. On the other hand, the disease not unfrequently comes on insidiously in persons who are weak and anæmic or otherwise in enfeebled health, or suffering, it may be, from overwork and anxiety, and in whom no true causative rheumatic influence can be discovered.

*Morbid anatomy.*—In rheumatoid arthritis the morbid processes are confined to the articular cartilages and synovial fringes. The central areas of the cartilages, to a variable but gradually increasing extent, acquire a velvety or villous character, get worn down by degrees, and finally disappear, leaving the subjacent bone exposed, which then assumes an ivory-like compactness and smoothness. But while the central portions are thus disappearing, the margins form nodular outgrowths of extreme irregularity, in size, shape, and arrangement. The synovial fringes take part in the hypertrophic process, and form bulbous or pyriform excrescences, varying in size, and often collected into complex clusters. They are at first fibrous, but soon become the seat of cartilaginous growth; and both they and the ecchondroses tend to ossify, and often after a while get converted wholly into bone. These outgrowths in some cases blend with the osseous structure of the epiphysis, in some cases remain connected with it by fibrous or cartilaginous pedicles, and occasionally break off. The gradual progress of the disease leads to the lateral expansion of the joint-surfaces, to extreme irregularity with nodular enlargement of the margins of the joint-ends of the bones, and to dislocation, deformity, and immobility. All joints are liable to be thus affected—those of the hands and feet, those of the arms and legs, those of the jaws, and even those of the spine. The early changes which take place in the cartilages in this affection are enlargement and proliferation of the cartilage-cells. In the central areas of opposed cartilages, where they are subject to constant mutual pressure, the enlarging cavities which contain the multiplying cells communicate with one another in vertical linear series, and opening

at the surface discharge their cellular contents into the synovial cavity ; by this means the hyaline substance becomes honeycombed by vertical pits, or split into vertical columns, and thus acquires its characteristic velvety appearance. The proliferation, however, of the cartilage-cells at the periphery (where growth is less interfered with) and of the synovial fringes results in permanent overgrowth of these parts, and in that further development of them which has been described.

*Symptoms and progress.*—The symptoms of rheumatoid arthritis are mainly those due to the gradual advance of deformity, dislocation, and loss of mobility in the affected joints, and to a tendency to gradual implication of most or all of the joints of the body. But with these are associated : pain and tenderness, rarely acute, in the affected parts coming on at irregular intervals and attended with febrile disturbance ; wasting of the muscles connected with the diseased joints, with spasmodic cram-plike pains in them ; and anæmia.

The disease, as has been stated, may follow immediately or remotely on an attack of acute rheumatism ; but in many cases it is chronic or sub-acute from the beginning. The patient, probably after a period of vague ill-health, complains of slight pain, tenderness and swelling in one or more of the joints, usually the knuckles, wrists, or knees, and of slight feverishness ; which symptoms, with rest and confinement to the house, possibly after a time subside. Then, after a short interval, the phenomena recur, probably with greater intensity ; and possibly other joints besides those first affected now become implicated. Again, perhaps, the symptoms subside. These attacks, however, continue to recur for the most part at shorter and shorter intervals, to implicate a gradually increasing number of joints, to leave them (in the intervals of subsidence) still swollen and tender, and to render them more and more useless. At length, after the lapse of some months, or it may be years, the patient becomes thoroughly crippled ; most of his joints, or all of them, are swollen, distorted, and more or less rigidly fixed ; all his muscles are wasted ; and his arthritic and muscular pains, now never wholly absent, are liable to frequent exacerbations, especially in connection with changes of temperature.

Rheumatoid arthritis usually commences in the hands, and more especially in the metacarpo-phalangeal joints of the fore, middle, and ring fingers ; the wrists and knees are also early implicated. The upper extremities as a rule suffer before the lower extremities ; and, although the metatarso-phalangeal joint of the great toe generally becomes affected in the course of the complaint, it is rarely or never the primary seat of attack. The articulations of the jaws and of the spine are for the most part implicated at a late period. The nodulated condition of the joint-ends of the bones is usually most distinctly marked in the finger-joints, the ball of the great toe, the wrists, elbows, and knees ; it is in these same joints, too, and in the hips, that imperfect dislocations most commonly occur. When the joints are rigid and fixed, they usually occupy the position of flexion ; the thighs are flexed on the abdomen, the legs on the thighs, and the fore-arms on

the upper arms—in the last case with some degree of pronation. The hands generally continue in a straight line with the fore-arms, or present some degree of tilting towards the ulnar side, but the fingers acquire various and strange distortions. The most frequent form is that in which, while the first and third phalanges are flexed, the second or intermediate phalanx is extended. The thumb is usually extended. Rheumatoid arthritis, though generally a progressive disease, occasionally remains limited to one or two joints, or becomes arrested in its progress, or even (so far as the structural changes which have taken place permit) undergoes cure.

*Pathology.*—The relation between rheumatoid arthritis and acute rheumatism is not easy to determine. It is quite certain that acute rheumatism very seldom induces the characteristic morbid processes of the former disease; and that rheumatoid arthritis is rarely attended with the profuse perspirations, the febrile urine, and the visceral complications which belong to acute rheumatism. On the other hand, rheumatoid arthritis is essentially an inflammation of the very structures which are mainly implicated in acute rheumatism; the joints become successively and symmetrically involved, as they do also in the latter disease; and, with reference to the absence of sour perspirations and the like, it must not be forgotten that these may be entirely absent in cases of chronic, sub-acute, or muscular rheumatism; and, as regards visceral complications, Trousseau shows that peri- and endo-carditis are sometimes present in these cases, and that even cerebral mischief occasionally supervenes. Moreover, as Garrod points out, inflammation of the sclerotic and other fibrous textures now and then attends rheumatoid arthritis. On the whole, we are inclined to regard it as a chronic inflammatory process, which is not necessarily, but is in a large number of cases, a sequela of acute rheumatism.

*Treatment.*—For the general treatment of rheumatoid arthritis we must refer to what has already been said in reference to the treatment of acute rheumatism. For the most part, however, we must trust to local measures and to constitutional treatment calculated to improve the general health of the patient. Locally, friction, counter-irritation, the inunction of the parts with preparations of iodine or mercury, the maintenance of the joints in one position by suitable apparatus, are all more or less important. Hot fomentations, again, are valuable, and especially perhaps (as recommended by Trousseau) the burying of the joint in sand heated up to  $140^{\circ}$  or  $150^{\circ}$ , keeping it there for an hour or two at a time, and repeating the operation three times a day.

---

### III. GOUT (*Podagra*)

*Definition.*—Gout is characterised by the deposition of urate of soda in a crystalline form in the cartilages and other textures of joints, and elsewhere among the fibrous tissues, and by recurrent attacks of articular

inflammation. It is usually attended also with constitutional symptoms and grave lesions of important organs.

*Causation.*—Gout is mainly a disease of middle and advanced life, and of the male sex, and generally comes on between the ages of thirty and forty-five. It is sometimes, however, met with at or about the period of puberty, and has occasionally made its appearance as late as the eightieth or even ninetieth year. In women it rarely shows itself until after the cessation of the menstrual flow. The influence of hereditary predisposition in the production of disease is probably nowhere more clearly evinced than in the history of gout; and, indeed, Dr. Garrod's experience leads him to the belief that more than half the total number of gouty patients have clearly inherited the gouty proclivity from their parents. On the other hand, it is certain that gout is largely induced by habits of life, and that, even where an hereditary taint exists, the influence of habits in accelerating the first attack or in postponing it, or even in preventing the occurrence of the disease, is still very considerable. As regards habits, it seems to be universally admitted that long-continued indulgence in alcoholic beverages, long-continued over-eating, especially of animal food and of rich dishes, and prolonged insufficiency of exercise, are (especially in combination) powerful agents in the causation of gout. It is, however, generally held that all alcoholic beverages are not equally injurious in this respect: that the distilled spirits are comparatively innocuous; that the light wines—claret, hock, moselle, and the like—are also fairly wholesome; but that the strong wines—sherry and madeira, and above all port—and malt liquors, are all virulent gout-producers. But on what, it may be asked, do the injurious effects of alcoholic beverages depend? If, as seems reasonable to assume, they are due to the alcohol which they contain, how can we accept the statement that the distilled spirits are almost harmless, while bitter ale and porter are highly poisonous? If, on the other hand, the alcoholic constituent be acquitted, must we refer them to the comparatively simple matters which give to alcoholic beverages their respective flavours, their colours, or their body—matters which are, most of them, not special to such beverages, are most of them certainly not unwholesome, and individually form an insignificant percentage of the whole? We must confess our distrust of the evidence which, while accusing alcoholic drinks of causing gout, acquits the alcohol itself. On similar grounds we venture to submit, notwithstanding almost universal testimony to the contrary, that port is no more injurious than sherry or madeira, or other wines of equal strength. It is probably less in consequence of the port which they drink than of the association in their case of over-drinking, over-feeding, and want of exercise, that the higher classes suffer more frequently from gout than those who occupy a lower station of life. It must be added that fatigue, exposure, indigestion, and whatever impairs the health, and injuries inflicted on joints, are all apt to bring on attacks of gout in those who are liable to the disease. The impregnation of the system with lead appears to be peculiarly powerful in inducing a susceptibility to gout.

*Morbid anatomy.*—The morbid phenomena of gout are chiefly manifested in the joints and surrounding tissues. The earliest appearances are furnished by the superficial portions of the articular cartilages, which seem dusted, so to speak, with spots and patches of an opaque white colour. As the morbid process extends, the cartilages become more and more generally infiltrated, until they look like a mere mortary incrustation of the joint-surfaces of the bones. Later still, similar mortary patches appear imbedded in the substance of the synovial membranes, and gradually involve them more or less completely; and at the same time, or later, masses (which eventually vary perhaps from the size of a pea to that of a filbert) accumulate in the substance of the soft tissues surrounding the joints, in the bursæ, and in the cancellous tissue of the subjacent bones. The changes do not end here. The infiltrated cartilages lose their vitality, become brittle, gradually eroded, and finally removed, exposing the bone beneath, which itself may sooner or later undergo destructive changes. The margins of the affected cartilages, on the other hand, not unfrequently become irritated into overgrowth, and form nodular enlargements like those of rheumatoid arthritis. The accumulations of mortary matter in the tissues about the joints, which constitute *chalk-stones* or *tophi*, gradually provoke erosion of the swollen and congested tissues which cover them, and finally an opening is formed through which they escape. The appearances above described are due to the deposition in the substance of the cartilages, and elsewhere where such deposits are found, of needle-like crystals of urate of soda, arranged for the most part in dense, opaque, stellate clusters. This deposition appears to commence within the cells, and, although the needle-like rays extend thence into the surrounding intercellular substance, it is still to the cells that the crystalline formation is mainly confined. Gouty formations, as a rule, first manifest themselves in connection with the metatarso-phalangeal joints of the great toes, usually the right, and may remain thus limited for a considerable length of time. But gradually other joints (and for the most part with more or less symmetry of arrangement) become involved—the smaller ones, as a rule, first, the larger ones at a later period. Thus, after the metatarso-phalangeal joints of the great toes, the other toe-joints and the joints of the tarsus, fingers, and carpus, the sterno-clavicular articulations, the ankles and wrists, the knees and elbows, and finally the hips and shoulders, and other joints, become successively the seats of disease. The joints connected with the laryngeal cartilages also occasionally suffer. Gouty deposits, moreover, are apt to form along tendons, chiefly in the neighbourhood of gouty joints; beneath the periosteum of the tibiæ and other bones; in the course of the smaller vessels and nerves; and in connection with the perichondrium of the external ear, the tarsal cartilages, and the sclerotic coat of the eye. In the ear they mainly affect the surface of the helix; in the tarsal cartilages, those portions which immediately adjoin the edges of the palpebral orifice.

The ultimate effects of gout upon the joints are in most cases very serious. They get irregularly swollen, partly from inflammatory and gouty

infiltration of the tissues which surround them, partly from the changes which have been going on in their interior. Accordingly the irregularity is not, as in rheumatoid arthritis, limited to the joint-ends of bones, but occupies the intermediate regions at least equally, and probably in a still greater degree. The articulations become more or less fixed, generally in some inconvenient position, and may even be dislocated; these results being due in various degrees to the changes which have taken place in the soft tissues around, to uratic infiltration and loss of suppleness in the synovial membranes and ligaments, and to actual ankylosis, which sometimes follows the complete removal of the cartilages. Chalk-stones form in the tissues external to the joint-cavities, adding to the apparent bulk of the joints and to their knotty irregularity, and finally become discharged through ulcerated openings, which, still secreting large quantities of chalky matter, may remain patent for years. The deformities and other ulterior changes here enumerated occur most frequently, earliest, and with greatest severity, in the joints of the hand; next in order in those of the feet; then in the wrists, elbows, ankles, and knees; and finally in the hips and shoulders.

It is rare to find in the necropsy of gouty persons that all other organs save those of which the morbid conditions have just been described are in a perfectly healthy condition. It could scarcely be expected, indeed, when one looks to the circumstances under which, as a rule, gout arises, that the internal viscera should escape those degenerative changes which so commonly follow long-continued persistence in bad habits, or attend that tendency to premature decay which some of us unfortunately inherit. It is not surprising, therefore, that gouty patients are liable to have degenerated arteries, valvular lesions and other morbid conditions of the heart, emphysema of the lungs, cirrhotic liver, and contracted granular kidneys. The last lesion, indeed, is so common in gout that it is not unfrequently termed the 'gouty kidney.' The kidneys of gouty patients, moreover, often present, especially in the cones, linear aggregations of a buff-coloured material, which is, in fact, a deposit of urate of soda, either in stellate crystals in the matrix, or in an amorphous form in the tubules. Concretions of the same material sometimes adhere to the mammillary processes. These precipitates are not, however, characteristic of gout, and are frequently found in persons who have no gouty tendency, and even in newborn children.

*Symptoms and progress.*—It has been distinctly shown by post-mortem examination that the gouty deposit takes place in the articular cartilages long before the joints become inflamed or give any clinical evidence of the nature of the process which is going on in them—a fact which is confirmed by the total freedom from inflammation and pain which usually attends the formation of those uratic concretions which are met with in connection with the aural cartilages and periosteum. And hence it may be assumed that at any rate a very large proportion of those who ultimately become distinctly gouty have been really gouty for a considerable time previously to the first decided outbreak; and hence also it is easy to understand that

in many cases the first so-called 'attack' may have been preceded by premonitory symptoms, such as occasional pain or tenderness in one or both great toes, or others of the smaller joints, such as those of the fingers, wrists, ankles, or clavicles.

The first 'attack of gout' almost always comes on suddenly, with pain and swelling in the ball of one of the great toes, usually the right. Moreover, it occurs for the most part early in the year, and almost without exception in the night time. The patient goes to bed probably in his usual health, but wakes about two or three o'clock in the morning with severe pain in the metatarso-phalangeal joint of one of his great toes. The agony is sometimes so intense that he dares not move the affected limb; he cannot bear the pressure of the bed-clothes, or even the slightest jar to his bed or the slightest movement in his chamber; his sufferings, too, are often aggravated by cramps and involuntary startings in the muscles of the leg: he becomes restless and hot, shivers, sometimes has repeated rigors, and after tossing about for some hours falls into a perspiration; and then, somewhere about the time when he should be thinking of getting up, he falls into a gentle sleep, from which, in the course of a few hours, he awakes, refreshed and comparatively easy, but with the great-toe joint swollen, tense, and vividly red, and with the superficial veins of the foot, and probably some of those extending up the leg, unusually distinct and full. He most likely continues comparatively well throughout the day, and may even be able to limp about on his maimed limb; but with the advance of evening, or it may be in the early hours of the ensuing morning, he has a recurrence of the local pain and febrile symptoms which marked the first attack, to be again followed, after the lapse of a few hours, by a second intermission. These nocturnal exacerbations, succeeded by matutinal remissions (lasting usually till evening), come on with comparative intensity for two or three successive nights, and then gradually diminish in severity until at the end probably of a week or ten days all febrile symptoms and all acute suffering have passed away. But the affected joint probably remains swollen, weak, and tender for a week or two longer. During the attack, the ball of the toe becomes, as has been stated, tense, swollen, vividly red, generally shiny, and exquisitely painful and tender. Most of these conditions attain their maximum usually by about the second day, after which the pain and tenderness gradually subside, and the redness acquires a dusky hue; but the swelling probably still increases for a time, and even extends far beyond the limits of the seat of inflammation. Much of this, indeed, is now due to simple œdema, and the parts pit on pressure. The swelling disappears in its turn and desquamation follows. The febrile symptoms, from which the patient suffers during his attack, are, as has been indicated, of a remittent type, and attended not only with shiverings or rigors and perspirations, but frequently also with furred tongue, loss of appetite, thirst, constipation, and a febrile condition of urine.

It occasionally happens: that even in the first attack of gout both great toes are simultaneously or sequentially implicated, or that not only the toes, but the ankles, knees, and other joints successively suffer, in which

case especially the affection may present a close resemblance to acute rheumatism ; or, again, that the first attack, instead of subsiding speedily, as it usually does, continues by a series of successive outbreaks of no great intensity in the same joint for weeks or months. It sometimes also happens that the first attack of gout is in the ankle, knee, or some other joint than that of the toe—a circumstance which in some cases is obviously due to an injury or some other lesion of the part.

The first attack of gout may also be the last. But far more commonly a second attack supervenes sooner or later, occasionally not for eight or ten years, sometimes after an interval of a few months only, most frequently at the end of a year or two. To the second attack other attacks succeed, at first separated from one another by intervals of probably about twelve or six months, but gradually approaching one another until at length the patient, though still liable to exacerbations, is perchance never actually free from suffering. Further, each successive attack, as a rule, implicates a larger and larger number of joints ; those joints, however, which have been most frequently affected generally suffering most severely. Gradually these grow lumpy, deformed, and rigid ; the patient becomes more and more crippled ; chalk-stones form and discharge themselves through ulcerated openings ; the general health deteriorates ; and death, usually dependent on some visceral complication, finally ends the scene. The pain which attends the later attacks of gout, although more continuous, is rarely so acute as that of the earlier outbreaks ; and, further, the degree of disorganisation of joints and the amount of urate of soda deposited in or about them are by no means necessarily related to the frequency or severity of the attacks of inflammation from which the joints have suffered.

The condition of the urine in gout, which has been carefully investigated by Dr. Garrod, has already been referred to. During the febrile paroxysms it is scanty and high-coloured, of high specific gravity, and generally deposits on cooling an abundant sediment. It contains relatively to its bulk an excess of urates ; but the total amount of these passed in the twenty-four hours is absolutely less than in health. The urea is also probably somewhat diminished. In the chronic form of the disease the urine is pale, abundant, of low specific gravity, generally yielding no deposit, and presenting (as in the febrile stage) a diminished daily quantity of urates and urea. It often contains a small amount of albumen, with hyaline or granular casts. The condition of the blood has also been investigated by Dr. Garrod, who finds : that during the inflammatory attacks of acute gout it contains urate of soda in relatively large abundance, while none can be detected in it previous to the occurrence of inflammation or after its subsidence ; but that, when the gout assumes a chronic or inveterate character urate of soda is present in the blood both during the exacerbations and in the intervals. He has also found in the blood oxalic acid, which he refers to the decomposition of the retained uric acid, and urea, the presence of which is probably always dependent on associated renal disease.

In the foregoing account many of those phenomena which by some

authors are regarded as among the most important in the history of gout have been passed over in almost complete silence. We refer, on the one hand, to the premonitory symptoms referrible to functional lesions of various organs ; and, on the other, to the various sequelæ or complications which from time to time present themselves. Gouty persons are usually dyspeptic ; and it is not unnatural, therefore, that dyspeptic symptoms should in a large number of cases precede the gouty paroxysms, and even persist during the intervals between successive attacks. Among the premonitory symptoms, therefore, may be enumerated epigastric discomfort, pain, flatulence, and eructation, with constipation or disturbance of the bowels, palpitation, dyspnoea, headache, drowsiness, restlessness, moroseness, irritability, and violence of temper. Such symptoms often attend the gouty outbreak ; but, on the other hand, they are said frequently to be removed by it. The sequelæ and complications of gout are numerous, and may be considered *seriatim* in connection with the organs which are their seat. In connection with the nervous system occur vertigo, headache, convulsions, mania, apoplexy, anæsthesia, paralysis, hyperæsthesia, lumbago, sciatica, and various other neuralgic pains ; in connection with the vascular system, palpitation, syncope, angina pectoris, and various forms of structural cardiac disease ; in connection with the lungs, asthma, bronchitis, and emphysema ; in connection with the gastro-intestinal tract, dyspepsia, gastralgia, irregularity of bowels, and hemorrhoids. Further, the liver not unfrequently becomes indurated or cirrhotic, and jaundice, ascites, or melæna may ensue ; the kidneys in a large number of cases get contracted, granular, and incompetent, and the patient tends to suffer from the usual symptoms of chronic Bright's disease ; the bladder becomes irritable or inflamed ; concretions form in the urinary passages, or mucous or purulent discharges take place from them ; and lastly, skin affections often arise, especially perhaps chronic eczema and psoriasis. But none of the symptoms or lesions here enumerated is peculiar to gout ; and their frequent co-existence with it is doubtless in large measure dependent on the fact that sufferers from gout are on the whole persons whose internal organs are in a greater or less degree in an abnormal condition, and whose bodily functions tend, therefore, to be imperfectly performed. It is asserted that, from exposure to cold or other causes, gouty inflammation is apt to subside suddenly, and its subsidence to be followed by grave symptoms referrible to the stomach, heart, or nervous system. This metastatic affection, of which our knowledge is in every respect extremely unsatisfactory, is termed 'retrocedent gout.'

Gout is in general easy of diagnosis ; it may, however, under various circumstances, be readily confounded with rheumatism or rheumatoid arthritis. We do not propose to discuss the many pathological and clinical differences which exist between these several affections. But we may recall to mind, as being specially distinctive of gout : its tendency to attack the smaller joints and lower extremities in the first instance, and mainly the metatarso-phalangeal joint of the great toe ; the formation of chalk-stones, in connection not only with the joints, but with the peri-

chondrium of the cartilages of the ears and eyelids, and in other superficial positions, where they may be easily recognised ; and the presence of urate of soda in the blood. Superficial uratic concretions may be easily removed, wholly or in part, with the point of a lancet and submitted to microscopic examination, when they will be found to consist mainly of the characteristic needle-like crystals, more or less thickly aggregated. For the purpose of testing the condition of the serum of the blood, Dr. Garrod's method may be adopted. It is as follows :—about two drachms either of the serum furnished by the blood on standing, or of the fluid raised by a blister, are to be placed in a flat glass dish, somewhat larger than a watch-glass, to be acidulated with acetic acid, and to have laid in it an ultimate fibre from a piece of linen cloth ; the prepared fluid is then to be allowed to stand until by evaporation it has been brought to the condition of a thin jelly, when, if there have been an undue amount of urates in the serum, the fibre will be found, on microscopic examination, studded with crystals of uric acid. To confirm the uratic character of the concretions removed from the surface of the helix, or of the crystals obtained from serum, recourse may be had to the murexide test, which consists in the development of a beautiful purple colour when a small quantity of the crystalline matter is heated with nitric acid on a porcelain surface and then treated with ammonia.

*Pathology.*—It is, we believe, now generally held that, although the deposition of urate of soda in the joints and elsewhere furnishes the only trustworthy evidence of the presence of gout, this deposition, the various premonitory symptoms, and the almost innumerable concurrent symptoms, complications, and sequelæ, are all traceable to the presence of urate of soda in the blood in undue quantity ; that the disease, in fact, looked at from an earlier stage than the joint-affection, is to be regarded not as a disease of the joints, but as an affection of the blood, a variety, as Dr. Murchison terms it, of 'lithæmia.' Dr. Murchison, who regards the presence of an excess of urates in the blood as the consequence of functional disturbance of the liver, would naturally consider gout to have some such relationship to the liver as uræmic dropsy has to the kidney. Dr. Garrod, on the other hand, apparently inclines to the belief that the kidney, failing from some unknown cause to act efficiently in the separation of urates from the blood, is the organ mainly at fault. In the one point of view the excess of urate of soda in the blood would be due to simple retention, in the other to its excessive formation ; but in either case the deposit of this substance in the joints would be regarded as eliminative, and in a sense curative. Dr. Garrod further regards the inflammation of gouty joints as destructive of urates in the blood of the inflamed part, and consequently indirectly in the whole mass of the blood. Against these hypotheses several important considerations may be adduced. First, as Dr. Garrod clearly admits, urate of soda is occasionally present in the blood in large quantities, and yet gout neither is present nor ensues ; second, although the presence of this salt in the blood seems to have been universally detected during the inflammatory paroxysms of

acute gout, and during both the exacerbations and the remissions of the chronic affection, Dr. Garrod points out expressly that it is not present during the intervals between the acute attacks, or during that period prior to any attack of inflammation in the course of which its slow deposition is taking place in the joints. Surely these facts are more in accordance with the hypothesis that the urate is formed in the tissues affected and thence shed into the blood, than with that which refers the local lesions to the precipitation of this salt from the already overcharged blood. We must confess, indeed, that our own views as to the pathology of gout are very nearly those which have been advocated by Dr. Ord. We are inclined to look upon this disease as arising from a tendency to a special form of degeneration in certain of the fibroid textures of the body, derived by inheritance or acquired by habits of life—a degeneration characterised by the excessive formation of urate of soda in the implicated tissues, whence, on the one hand, it is discharged into the blood, on the other deposited here and there, and especially in those parts (as cartilage) which are least well supplied with vessels and lymphatics. And we are disposed to regard the so-called ‘attacks of gout’ as being in some sense accidental, predisposed to by the gouty deposits which have already accumulated in the part, and determined by accidental injuries, exposure to cold, and generally any of those conditions which are apt to excite local inflammation. If this view be correct, we should expect to find a specially abundant formation of urate of soda in gouty tissues during the period of inflammation in them, and a specially abundant discharge of urates thence into the veins or lymphatics, or both. We know that Dr. Garrod’s assertion with regard to the absence of urates from the serum furnished by blisters applied over the inflamed joints is apparently opposed to this hypothesis; on the other hand, Dr. Ord quotes facts which are in its favour; and it must be added that the *experimentum crucis*, namely, the chemical examination of the blood obtained direct from the veins leading from the inflamed parts, and its comparison with the blood of other vessels, has not yet been performed.

*Treatment.*—In reference to the treatment of gout we have to consider : 1. What should be done during the inflammatory attacks ; 2. What should be done during the intervening periods.

As regards the first question, much difference of opinion prevails. Trousseau, following Sydenham, regards all attempts, local or general, to relieve pain or cut short the attack as prejudicial. These views, however, are not generally held, at least in their integrity ; and most physicians, we believe, would now rarely hesitate to make use of those remedies the efficacy of which has been proved by experience. The most valuable of these is colchicum, which may be given in any of the pharmacopœial forms, and of which the wine may be administered in doses of from 10 to 30 minims three times a day. Veratria has similar but less powerful anti-podagral properties. Quinine is another remedy the value of which in largish doses, 5 or 10 grains, three times a day, has been lauded. Purgatives are often of great value ; among such drugs colocynth is

believed to be specially efficacious ; and indeed the combination of quinine and colocynth forms the basis of some of the best known nostrums. Alkalies, again, mainly the carbonates or the salts formed by their union with the vegetable acids, are generally regarded as useful. The lithia-salts are especially recommended by Dr. Garrod in consequence of their solvent power over uratic salts. When the inflammatory state of the joints assumes a chronic character, the above remedies may be employed, but with less vigour ; and at this time guaiacum and particularly iodide of potassium are often of great value. Generally it may be said that during the gouty paroxysm, the emunctories, above all the kidneys, should be encouraged to free action ; the bowels kept freely open ; perspiration promoted ; and the flow of urine increased by the drinking of abundant diluents and the use of the alkaline diuretics. Dyspeptic symptoms should be counteracted, for which purpose the alkalies are again serviceable ; and these, combined with colchicum, and either rhubarb or a vegetable bitter, will usually prove the most suitable medicinal agents. As regards local treatment, the affected joints should be kept at perfect rest, and if necessary by mechanical means. Leeches and cold lotions are generally deprecated, and warmth is not always agreeable ; still the investment of the joints in cotton-wool, or in bran poultices, sometimes gives comfort, and especially the application of blisters, or the wrapping of the parts in flannel or cotton-wool steeped in rectified spirit and covered with oiled silk or gutta-percha.

The question, however, of what should be done in the intervals to prevent the recurrence of the attacks is the more important one ; and the answer in general terms is not difficult. The patient should make an important reduction in the amount of alcoholic stimulants which he is in the habit of taking, or, if he can do so without detriment to his digestion and to his general health, give them up altogether ; he should refrain from excesses in eating, and especially in eating flesh and rich articles of diet ; he should, in fact, while not starving himself or so restricting his choice of viands as to render food unpalatable, reduce his daily consumption to the amount which nature requires, and restrict himself to what is wholesome and nutritious ; he should take daily exercise, not, however, over-fatiguing himself, or insisting on overcoming by exercise the pain or tenderness of an already gout-stricken member ; he should dress himself warmly, and guard against unnecessary exposure to vicissitudes of temperature ; he should avoid as far as possible all overwork of the mind as well as of the body, and mental anxiety ; if he suffer from indigestion or other ailment, this should be treated. Further, tonics, such as iron and quinine, and periodical baths, especially the hot bath, the hot-air, vapour or Turkish bath, and change of air and scene, are often of the greatest value in the treatment of those who suffer from chronic gout. It must, however, be admitted that the rules here laid down cannot, unfortunately, always be enforced ; and further, that their strict enforcement will, in most cases, diminish only, but not eradicate, the gouty tendency.

It is in cases of this sort that recourse is constantly had to mineral

waters. There can be no harm in taking alkaline or other waters, provided the nature of the ingredients contained in them is compatible with the patient's requirements. The main benefits, however, which result from this practice are due to change of air and scene, to the bathing, and to the dietetic and other restrictions which are usually enjoined and submitted to.

#### IV. RICKETS (*Rachitis*)

*Definition.*—This is a disease of early childhood, characterised mainly by softening of the bones, with enlargement of the joint-ends of the long bones, enlargement of the liver and spleen, and coincident symptoms of general ill-health.

*Causation.*—Rickets rarely shows itself prior to the sixth month after birth, or later than the second year, and most commonly comes on between the twelfth and eighteenth month. Children, however, are said to have been born rickety, and in rare cases the supervention of the disease has been delayed to the fifth or sixth year. Many causes have been assigned for rickets, and yet it must be confessed that a good deal of mystery still enshrouds its etiology. It does not appear to be hereditary in the sense that rickety children are the offspring of rickety parents or even of parents who are scrofulous or syphilitic; it nevertheless happens that rickets is often the appanage of certain families of children, and in such cases (according to Sir W. Jenner) it is common for the younger members to suffer exclusively, or more severely than their elder brothers or sisters. Poverty and hard living would seem to exert some influence in its production; at all events, the children of the poorer classes are more frequent sufferers than those who are brought up in luxury and comfort. There is no doubt, indeed, that defective hygienic conditions generally favour it; but among these unsuitable feeding is probably by far the most efficient. A large proportion of rickety children have been brought up by hand, or have derived an insufficient quantity of inferior milk from inefficient nurses, and have at the same time been supplied with food which is more or less unsuitable, or even directly injurious. It is thus, probably, that delicate mothers are often indirectly answerable for the rickety state of their offspring. The influence of improper diet in the causation of rickets seems proved by the experiments conducted by M. Guérin on puppies. By removing these animals from the mother, weaning them and feeding them on raw flesh (a food unsuited for them at that early age), he rendered them in the course of four or five months unmistakably rickety. Rickets is said to be especially common in damp and cold climates.

*Morbid anatomy and pathology.*—The morbid changes which attend and characterise rickets are limited almost exclusively to the bones, liver, and spleen. And of these by far the most interesting and important are those which have their seat in the osseous system. The rickety process attacks all bones simultaneously, or nearly so, and in about an equal degree. It can, however, be best studied in the long bones. In these the whole

tissue tends sooner or later to become involved, but those parts in which growth is taking place most actively (namely, the extremities and the outer surface) are primarily and principally affected. For the following account of the morbid anatomy of rickets we are mainly indebted to the investigations of MM. Cornil and Ranvier. In the normal process by which ossification extends from the already ossified shaft into the cartilaginous end, the line of advance is even and well-defined, the cartilaginous tissue immediately bounding it (to the thickness of about one-twentieth of an inch) presenting a peculiar bluish transparent aspect. In this bluish cartilaginous lamina the changes preliminary to ossification are going on actively. But it is in the layer of bone immediately subjacent to it that the earliest stage of actual ossification is to be recognised. In the former of these laminae we find the encapsuled cartilage-cells becoming larger and larger at the expense of the surrounding hyaline tissue, and giving origin to daughter-cells which themselves become encapsuled, but sooner or later yield large numbers of cells having the embryonic character. During this process the cavities in which the cells are imbedded increase in size, and presently communicate more or less freely with one another, thus forming branching channels or alveoli full of embryonic cells, and separated from one another by areolæ formed of the surviving remnants of the hyaline matrix. In the latter of the laminae above referred to, earthy matter is being deposited in the substance of these areolæ, and vessels are developing in the alveoli from the embryonic tissue or marrow which they contain. A little deeper, the concentric zones of earthy matter and stellate corpuscles which, by their presence within them, convert the alveoli into Haversian systems may be recognised in process of formation.

In rickets, the bluish cartilaginous lamina becomes very irregular in form and thickness—the chief irregularity being manifested by its under surface, whence numerous processes extend into the subjacent tissue, in which also isolated patches of cartilage may sometimes be detected. The chief departure from health, however, is manifested by a lamina, corresponding in position to the second of the laminae above described, which lies between the cartilage and the ossified extremity of the shaft (from which it is imperfectly divided), and the thickness of which varies, and in some cases is very considerable. This lamina has a marked resemblance to sponge, being, like it, both cavernous and elastic; but it is highly vascular, and its alveoli are filled with a sanguineous pulp. Microscopic examination shows the dependence of these abnormal appearances upon certain modifications of the process of ossification. In the bluish cartilaginous lamina the mother-cells give origin to daughter-cells, which become encapsuled; but these, while still of large size, become encrusted with calcareous granules, which are also deposited in the intervening cartilaginous matrix. Their further proliferation is thus to a large extent impeded, and they fail to regulate the subsequent process of alveolation, which takes place as it were without discrimination—irregular cavities being formed here and there by the liquefaction of the hyaline cartilage and the contained calcareous capsules, and irregular trabeculae resulting

from the persistence of identical tissues in the intervals between them. The essential departure from health seems so far to consist in calcification of the capsules of the daughter-cells, and in the fact that the areolæ are formed, not of hyaline material only, but of this together with cartilage-cells, which are of large size, and encrusted with earthy salts. In the spongy tissue beneath the same process goes on; the alveoli (instead of getting smaller, as they do in healthy ossification, from the formation of concentric laminæ) grow larger and larger, the areolæ undergoing corresponding rarefaction and destruction, and becoming at the same time more and more calcareous. The medulla which occupies the cavities is richly provided with large delicate-walled vessels, and an abundance of ordinary granulation or embryonic tissue. The morbid processes which go on between the shaft and the periosteum are (allowing for the anatomical differences between cartilage and periosteum) identical with those just described. The periosteum in the normal condition may be readily stripped as a membranous lamina from the surface beneath. In rickets a soft spongy formation, of variable and often considerable thickness, intervenes between them. This consists of refractive trabeculæ, formed partly of intercellular substance, partly of connective-tissue corpuscles, and infiltrated to a greater or less extent with earthy matter; and of intercommunicating medullary spaces filled with embryonic tissue and newly-formed blood-vessels. It is obvious that the areolæ or trabeculæ, whether formed from cartilage at the epiphysial extremities of the bone, or from periosteum at its surface, and whether infiltrated with earthy matter or not, are continuous with the solid framework of the completely formed bone-tissue underneath; and that the embryonic or granulation tissue which fills their alveoli is continuous with the normal medullary matter occupying the Haversian canals, medullary spaces, and central cavity of the bone. And it may be added that, if the rickety condition persist and extend, not only do the alveoli of the newly-formed tissue enlarge at the expense of the trabeculæ between them, but the medullary tissue of the normal bone-cavities gradually acquires the embryonic character, the bone-tissue melts away around it, the Haversian canals and all other spaces consequently undergo enlargement, and general rarefaction ensues. Sir W. Jenner observes that the bones of healthy children yield about 37 per cent. of organic and 63 of earthy matter, whereas those of rickety children sometimes yield as much as 79 per cent. of organic and only 21 of earthy matter.

The general consequences of rickets are that the bones thicken (a change which is especially evident in the joint-ends of the long bones and in the edges of the flat bones of the skull) and become soft, and consequently liable to bend, or to break with the so-called 'green-stick' fracture. The enlargements are most obvious at the wrist and ankle-joints, and at the elbows and knees; they are frequently also well shown at the junctions of the ribs with the costal cartilages, along the lines of the cranial sutures, and elsewhere where bones are in relation with epiphysial cartilages. The curvature of bones comes on somewhat later than their manifest thickening, and usually

proceeds from the lower part of the skeleton upwards. Its direction is determined partly by that of the normal curvatures of the bones, and partly by the direction and force of the mechanical influences which act upon them. The tibiæ and fibulæ usually bulge forwards and outwards, and the femora follow suit; when, however, the rickety condition appears late, the bending of the legs is often in the opposite direction, and the child becomes knock-kneed. The radius and ulna for the most part acquire a curve with the convexity facing backwards; but the shape of the humerus is often determined by the attachment of the deltoid. The shoulders get narrowed by the shortening of the clavicles due to exaggeration of their natural curves. The back becomes bent in the same sense, and often more or less twisted: by increase of the cervical curve the head tends to be thrown backwards, and the face to be directed upwards and forwards; exaggeration of the dorsal and lumbar curves is often attended with lateral deviation connected with rotation of the bodies of the vertebræ upon their axes. In children who have not yet walked the lumbar curvature is lost in that of the dorsal region, and both combine to form the segment of a circle with the concavity looking forwards. The shape of the chest in rachitic children becomes remarkably modified; the ribs sink in laterally, especially from about the third to the ninth, so that the transverse diameter is diminished in this situation, while the antero-posterior is correspondingly augmented and the sternum thrown forwards. There is usually also in the same part of the chest a well-marked vertical groove running down on either side, just external to the junctions of the ribs and cartilages. The form of the upper part of the chest, however, is slightly or not at all altered; while the lower part, owing to the presence of the liver, spleen, and other abdominal viscera, again expands, and its shape is pretty nearly normal. The changes which take place in the form of the pelvis are of great importance. The bones of the upper part get flattened and expanded by the pressure of the abdominal viscera upon them; but the weight of the spine above throws the sacrum forwards, and the pressure of the femora below causes an approximation of those parts of the pelvis which bound the acetabula; and the pelvic cavity consequently becomes contracted, and tends to assume a triangular form on transverse section. But the relative effects of these and other agencies are largely modified in different cases by a variety of circumstances, such as age, and the possession and use of the powers of walking, crawling, or sitting. The bones of the head and face share in the tendency to deformity. The fontanelles are slow to close, remaining open up to and beyond the second year; the head becomes large, flat on the top, elongated from before backwards, with projecting forehead and unusual prominence of the frontal and parietal eminences. The teeth are late in appearing, and, indeed, if none have been cut by the age of nine months it is a reason for at all events suspecting the presence of rickets. The teeth, moreover, are specially apt to decay and become loose. It will of course be understood that the deformities of the skeleton in rickety children are liable to innumerable variations from the types which have been enumerated; that in a large number of cases they never become

serious, and are probably confined to the bones of the legs and perhaps some few others ; while in some cases they assume such extreme proportions that they are not only a source of distress and misery, but are incompatible with the performance of some of the normal functions of life, or even with the maintenance of life.

After a time, which varies in different cases, the rickety condition ceases and the bones regain their earthy elements and their strength. The bone tissue, indeed, gets unnaturally strong and dense. In some cases slight degrees of curvature slowly disappear in the progress of growth ; more frequently, however, they are persistent, and there is more or less of permanent deformity.

Dr. Dickinson's observations seem to show that a morbid process, in some respects like that in the bones, goes on in the kidneys and lymphatic glands, and especially in the liver and spleen of rickety children ; and that these organs become enlarged and indurated, and the seat partly of interstitial development of fibroid tissue, partly of overgrowth of the glandular elements. The changes are transitory, and are accompanied by a deficiency of the earthy salts. They are quite distinct from amyloid or lardaceous degeneration.

Whatever the exciting cause of rickets may be, and however it acts, there can be little doubt that the morbid processes to which it gives rise in the several viscera which have been enumerated, and in the bones, have a close affinity with those of general subacute or chronic inflammation, and that the main incidents in them are an irritative overgrowth of the implicated tissues, and a modification or perversion of their normal nutrition.

*Symptoms and progress.*—In giving an account of the clinical phenomena of rickets, it is customary to enumerate a long series of precursory symptoms, the occurrence of which not only should excite suspicion of the impending danger, but is commonly regarded as a proof that rickets is the outcome of some cachexia or dyscrasia. The constitutional origin of the malady can scarcely be denied ; but it is certain that it must always have made some considerable progress before the deformity of the joint-ends of the long bones or of the chest, and the bending of limbs, become obvious, and that many, therefore, of the precursory symptoms belong properly to the earlier stages of the rickety process. Among these must probably be included catarrhal affections of the thoracic viscera and gastro-intestinal disturbance. But by far the most important and characteristic are : first, a febrile condition manifested by restlessness at night or during the hours devoted to sleep, intolerance of the bed-clothes, which the infant continually throws off, and profuse perspirations, mainly limited to the head and upper parts of the body ; and, second, general tenderness or soreness, due doubtless to general implication of the bones, and indicated by a gradually increasing unwillingness or fear to move or be moved, and a loss of enjoyment in the caresses and dancings which form so large a part of a healthy infant's life and happiness. The first distinct evidence, however, that the bones are undergoing serious change of structure is usually afforded by

the enlargement of the lower extremities of the radius and ulna, and by the simultaneous or shortly subsequent enlargement of the corresponding portions of the tibia and fibula, and of the knee and elbow joints. If the affection still proceeds, the shafts of the long bones and the spine acquire the alterations of form which have already been adverted to; the ribs fall in at the sides, the sternum protrudes anteriorly, and the pigeon-breasted condition results, in association with which the knoblike enlargement of the anterior extremities of the ribs on either side produces that characteristic appearance to which the name of the 'rickety necklace' or 'chaplet' has been applied; the pelvis gets distorted; and the bones of the head become affected, mainly, as has been pointed out, by thickening of their edges, protrusion of the parietal and frontal eminences, and unusual persistency of the fontanelles. But while all these deforming processes are going on with more or less uniformity and rapidity, the various symptoms which marked the beginning of the disease usually undergo aggravation; the fever becomes more intense, the pulse accelerated, the heat of skin augmented, the nocturnal perspirations more profuse, and the general tenderness more marked. Actual pain, indeed, often supervenes; and the fear or inability to move and the dread of being touched become much more apparent. In connection with these phenomena the appetite fails, there are thirst and irregularity of bowels, the urine is copious and contains a superabundance of phosphates, and the child undergoes rapid emaciation with disproportionate wasting and feebleness of the voluntary muscles; he acquires an anæmic or pallid, sad, anxious, wan aspect, and takes no interest in what is going on about him. During all this time, the abdomen becomes relatively large, and the liver and spleen will probably be found to be distinctly hypertrophied; indeed, the enlargement of these organs is sometimes one of the earliest indications that the child is rachitic. Ascites is sometimes a consequence of the hepatic affection. The influence of rickets on dentition has already been fully considered. According to MM. Rilliet and Barthez, whose opinions are confirmed by those of Dr. H. Roger, a blowing sound is so commonly audible over the cranial sutures of rachitic children that it may almost be regarded as diagnostic of the affection.

When rickets proves fatal, it is usually either by gradual asthenia connected with the advance of the disease and impairment of the digestive functions, or by thoracic complications, such as collapse of the lung-tissue, lobular pneumonia, or bronchitis—the accession as well as the gravity of which are largely dependent on the weakness, deformity, and consequent inefficiency of the thoracic walls. Other causes of death in rickety children are laryngismus stridulus, convulsions, and chronic hydrocephalus. The duration of rickets commonly ranges between six and twelve months at the end of which time the constitutional symptoms and those indicative of osseous inflammation subside.

Persons who have suffered from rickets in infancy not unfrequently acquire great strength of limb (muscle and bone), but they usually remain of low stature; and the deformities which take place at the time of their

malady only too commonly persist; whilst some (more especially those of the chest and pelvis) not unfrequently entail serious misery and danger in after-life.

In concluding this brief account of the symptoms of rickets, it is well to draw attention to the fact that the disease may be present in a slight degree (sufficient to cause manifest thickening of the wrists and ankles, and even bending of the tibiæ and thoracic walls) in children who maintain their vivacity and the aspect of almost perfect health.

*Treatment.*—It might be supposed, from the fact of the disappearance of phosphate of lime from the bones, that the administration of phosphate of lime is indicated in the treatment of rickets. Experience has not, however, confirmed this view; nor, indeed, does a correct interpretation of the pathological phenomena of the disease give it any sanction. The best medicinal remedies are tonics, such as iron and cinchona, and, above all, cod-liver oil. But these are valueless without the most careful attention to diet and hygiene. The diet should be at once nutritious, sufficiently abundant, and adapted to the age and circumstances of the child. For the young infant nothing can be more suitable than the healthy breast, or, failing that, ass's milk, or else cow's milk, or preserved Swiss milk, properly diluted, and mixed, it may be, with a certain proportion of biscuit powder. At a later age a moderate quantity of well-cooked meat, comprised in a dietary which combines all the other essential elements of food, namely, sugar, starch, and fat, and composed therefore largely of milk and bread and butter, should be administered. The child should be warmly clad, should occupy an airy but sufficiently warm room, be regularly bathed and well rubbed afterwards, and taken out habitually into the open air. Change of air, and especially residence on the sea-coast, are often of essential service. But, in addition to the above measures, it may be desirable to treat the symptoms which are so apt to accompany rickets; to improve the condition of the stomach, to regulate the action of the bowels, to reduce fever, and to combat pulmonary and other complications. And especially it is of paramount importance to prevent as far as we possibly can the supervention of deformity. To this end, our measures must be regulated by the age and peculiarities of the patient. It is impossible to go into detail without becoming unsuitably diffuse. We may, however, point out that the child should lie on a soft, well-made feather bed; that if it be quite young, it should not be allowed to sit up; and that if older (and the limbs give evidence of bending), it should be prevented from walking, and perhaps even from crawling. Mechanical appliances may be necessary to restrain undue locomotion.

## V. ACUTE RICKETS

*Definition.*—A disease of early childhood in which a rickety condition of bones is associated with more or less abundant hemorrhage beneath the periosteum.

*Causation.*—Acute rickets is regarded by Dr. Barlow,<sup>1</sup> in his excellent paper upon the subject, as a complex of rickets and scurvy. Rickets has no doubt been present in nearly all, if not in all, the cases hitherto recorded. But this has often been exceedingly slight; and the hemorrhages appear to have borne no relation to the extent or severity of the rickets. On the other hand, in many of the cases which Dr. Barlow quotes, the sub-periosteal hemorrhages have been associated with other symptoms indicative of the presence of purpura or scurvy. Moreover, the affected children had often been fed on unsuitable food, and have been benefited, if not cured, by anti-scorbutic remedies. He regards the disease, in fact, as essentially scurvy, and the rickets as little more than a merely accidental accompaniment of it. Acute rickets seems to affect both sexes equally, and to occur mainly between the ages of six and eighteen months.

*Morbid anatomy.*—The main phenomena observed after death have relation to the bones and periosteum. The periosteum, which is thick, congested and pulpy, is separated from the bone by a more or less considerable quantity of blood-clot, the condition of which varies according to the duration of the disease. The bone is smooth but brittle, and occasionally is found fractured—if it be a long bone, just before its junction with the epiphysis; if it be a rib, near its junction with its cartilage. The medulla of the bone is soft and red, and the trabecular tissue wasted. Further, blood is often extravasated into the connective tissue external to the periosteum, and among the deeper-seated muscles, and sanguinolent serum infiltrates the more superficial parts.

The sub-periosteal hemorrhages may occur in connection with any of the bones of the skeleton, but affect the lower limbs more frequently than the upper, and are occasionally met with in connection with the ribs, scapulæ, and bones of the skull. In the long bones the hemorrhage usually begins in the neighbourhood of the epiphyses, and may be limited thereto. And in many places, even where no hemorrhage has occurred, the periosteum is thick, soft, and congested.

The bones usually display more or less well-marked indications of the presence of rickets.

Few visceral lesions of importance have been detected; but not unfrequently there have been found petechial extravasations in connection with various organs.

*Symptoms and progress.*—The invasion of the disease may be sudden or gradual; and in the latter case is marked by fretfulness, associated with unaccountable pain and tenderness of the limbs. In its fully developed form the child is extremely irritable and fretful, indisposed to move or to allow itself to be touched, and apt to moan; its complexion is markedly anæmic, often sallow or muddy; and there is general emaciation. The affected limbs, however, are swollen, tense, and shining, usually pale though sometimes rosy, maintained immovably in the flexed or else in the extended position, and extremely tender. The swelling, for the most

<sup>1</sup> 'Med.-Chir. Trans.' vol. xlv.

part, is not symmetrical or generally distributed. The lower extremity suffers more than the arm, the thigh more than the leg, and the neighbourhood of the tibia more than that of the fibula. When the swelling is considerable and extensive it is difficult or impossible to determine the condition of the bone; but in the earlier stage of the disease, or at a later period when absorption has taken place to some extent, and in all cases in which there is comparative absence of œdema, the cylindrical swelling due to the sub-periosteal hemorrhage may be readily distinguished. The effusion of blood generally begins in the neighbourhood of the epiphyses, and it may be limited to this neighbourhood. In such cases the swelling may be mistaken for simple rickety enlargement of the joints; but its true nature will probably be revealed by its extreme tenderness, and by the fact that the swelling is not so much epiphysial as in the course of the adjoining portion of shaft. Occasionally in severe and advanced cases crepitus, due to fracture, may be detected towards the extremities of one or more of the affected bones. Swellings, also due to extravasation, may occasionally be observed in connection with the ribs, scapulæ, jaw-bones, and bones of the skull.

Among the variable symptoms occurring in acute rickets may be enumerated: petechial extravasations beneath the skin; stomatitis, or sponginess and bleeding of the gums; discharge of blood or albumen with the urine; and fever. In most cases there seems to have been some rise of temperature at some period or another of the disease, but it has seldom reached 103°. In some instances the temperature has remained normal from first to last. And in all there have been periods of apyrexia. There is generally copious sweating of the head. The appetite usually remains good.

The duration of the disease varies for the most part between two and three and a half months. It is very fatal, inasmuch as nearly one-fourth of the recorded cases have died. But for those who recover, recovery is generally complete.

*Treatment.*—This should be mainly anti-scorbutic. Dr. Barlow recommends ‘*locally*, during the acute stage, lint compresses and avoidance of movement; at a later period careful shampooing and douches; *internally*, the use of raw-meat juice, fresh milk, and orange juice, or of some other fresh raw vegetable, and from the first the access of as much fresh air as is possible.’

---

## VI. MOLLITIES OSSIUM (*Osteo-malacia*)

*Definition and causation.*—This affection has in many respects a close resemblance to rickets. It occurs, however, not in children, but in adults. It has been recognised, indeed, only in women, and for the most part in women who are bearing children.

*Morbid anatomy and pathology.*—Mollities ossium is characterised anatomically by progressive softening of the bones, sometimes of those of the whole skeleton, occasionally of a limited number only. The minute

changes appear to consist mainly in a progressive decalcification of the bony tissue, commencing from the Haversian canals and medullary spaces, and gradually involving the successive laminae of bone which surround them, until finally decalcification is complete. A sharp line generally marks the limit of the morbid process, the bone external to it being still normal, whilst that between it and the canal or cavity is converted into a kind of fibroid tissue, in which the bone-corpuscles are scarcely distinguishable. At a later period the portions of tissue first affected soften and liquefy. Attending these changes the smaller vessels become dilated, and the contents of the various cavities red and pulpy. The enfeebled bones are liable to all those bendings and imperfect fractures which also characterise rickety bones; but, owing to the long duration of the malady, and the extent to which softening takes place, the deformity which ensues is usually of the most aggravated kind and pretty universal. Trousseau maintains that *mollities ossium* is identical with rickets, allowance being made for difference of age, and for the fact that the active processes of growth have ceased when osteo-malacia makes its appearance. The anatomical details, however, of the two processes are manifestly different. It is supposed by Rindfleisch and some others that the decalcification is due to the action of some acid (carbonic or lactic) contained in the blood. The appearances are, no doubt, much like those which might be thus caused. There is no direct evidence, however, to support this view; and, indeed, Virchow has ascertained the existence of a strong alkaline reaction in the gelatine yielded by fresh bones affected with this disease.

*Symptoms and progress.*—The symptoms of osteo-malacia, like those of rickets, are often very insidious; and the disease may first reveal its presence by the occurrence of deformity and fracture of bones. Its progress, however, is usually attended, even from the beginning, with febrile disturbance and copious perspirations, and with tenderness and pain in the course of the affected bones. The pains are, in the first instance, vague and wandering, and of a shooting character. But they gradually become more or less intense; affect not only the limbs, but the trunk, head; and face; and are greatly aggravated by movement or pressure. They are often most severe in the joint-ends of long bones, and in the epiphysial ends of most bones. They may easily be mistaken at first for rheumatic or neuralgic pains. The urine contains an excess of phosphate of lime.

The progress of osteo-malacia is chronic; cases have been met with in which the disease has been prolonged for fourteen or fifteen years and upwards. Death usually takes place, however, at a much earlier date, and is generally due immediately to interference with the respiratory or circulatory functions. Recovery very rarely takes place, and never without persistent deformity. Trousseau has recorded a case or two of this kind.

*Treatment.*—No distinction need be drawn between the treatment of osteo-malacia and that of rickets. It was under the use of cod-liver oil that Trousseau's cases recovered.

VII. ACROMEGALY<sup>1</sup>

*Definition.*—The above name (derived from the Greek words, *ἄκρον*, extremity, and *μέγας*, large) has been given by Dr. Pierre Marie to a remarkable disease, characterised mainly by gradual symmetrical enlargement of the bones, chiefly of the hands and feet and of the lower jaw, and overgrowth of the soft tissues of the same parts.

*Causation.*—Only a very small number of cases of acromegaly have as yet been observed; but, so far as appears, the disease affects both sexes equally, begins between the ages of 20 and 30, is not hereditary, and arises independently of any obvious cause.

*Symptoms and progress.*—Acromegaly appears to come on slowly and insidiously, without pain, uneasiness, or signs of ill-health; and it is probably only after it has been in progress for some years that the patient observes that he requires larger boots and gloves than he formerly did, and a growing hypertrophic deformity of the face.

In a well-marked advanced case the condition of the patient will probably be as follows:—The hands and fingers are enormously large, the enlargement being mainly in breadth and in thickness, and due to overgrowth both of the bones and of the soft tissues. The fingers are thick and stumpy and stiff, the nails flat and relatively small; there is usually an accumulation of soft tissue on the inner side of the hypothenar eminence; and the folds and creases, especially on the palmar aspect, are coarse and large. The wrists, and to a less degree the lower parts of the forearms, are apt to share in the hypertrophic changes. The feet are in the same condition as the hands, and large fleshy pads are observable along their outer borders. The malleoli and ankles also suffer to some extent. The head itself presents little or no enlargement, excepting in the region of the frontal sinuses. The nose is increased in all its dimensions, and especially so towards the tip; the cheeks are elongated and flattened, the cheek-bones being prominent. But the most remarkable fact as regards the face is the great lengthening and prominence of its lower part, owing to hypertrophy of the lower jaw and of the lips. The enlargement of the lower jaw is general, and leads to widening of the intervals between the teeth, and to the protrusion of the dental arch forwards to such an extent that the lower teeth are far in advance of the upper. The lips are large and loose, and the lower one pendulous and everted. The tongue also undergoes hypertrophy in all its dimensions.

The affection is not strictly limited to the group of phenomena above described; but usually also, the upper part of the dorsal spine is curved forwards, or strongly rounded, so that the head seems buried between the shoulders, and the neck is short and thick; the sternum projects forwards, and the ensiform cartilage is large and prominent; the thorax is flattened from side to side, and consequently unusually deep;

<sup>1</sup> See cases by Hadden, Ballance, Godlee and Wilkes in the 'Clinical Society's Transactions,' and Marie's essay on Acromegaly in 'Brain' for July 1889.

and the clavicles, ribs and cartilages, and pelvic bones, are all more or less hypertrophied. The skin usually is dry, and, more especially around the eyes, of a dead-leaf hue.

Among other occasional symptoms of more or less importance, may be mentioned enlargement of joints and pains in them, thickening of the ears and eyelids and of their cartilages, headache, deafness, affection of sight going on to actual blindness (accompanied by optic neuritis, and said to be due to pressure exerted by the enlarged pituitary body), deepness or gruffness of voice determined by enlargement of the larynx and indistinctness of utterance dependent on the affection of the lips and tongue, loss of sexual power and desire, hypertrophy of the external organs of generation, and in women suppression of the menses.

The mind does not appear to suffer.

The disease lasts for many years, and it is not at all clear that it tends to shorten life.

*Morbid anatomy.*—Only one or two post-mortem examinations of cases of acromegaly have yet been made; from which it would seem that the enlargement of bones is mainly in their cancellous texture, that the thymus is persistent, and that the pituitary body becomes hypertrophied, its enlargement leading to great expansion of the sella turcica. The thyroid gland appears to be unaffected.

Of the *treatment* of the disease nothing is known.

## CHAP. VIII.—DISEASES OF THE NERVOUS SYSTEM

### I. INTRODUCTORY REMARKS

#### A. *Anatomy and Physiology*

THE nervous system comprises the cerebrum and cerebellum, with the various ganglia and commissures which belong to these bodies, the medulla oblongata, the spinal cord, the sympathetic ganglia, and the nerves which, springing from these several sources, are distributed throughout the organism. With the central organs are associated as important elements the various membranes and other structures which serve for their support and protection, and the arteries and veins which minister to their nutrition and functional activity.

1. *Membranes of brain and cord.*—The *cranial dura mater* is a thick, dense, inelastic, fibrous membrane, which by its outer surface adheres firmly to the bones of the skull; by its inner surface, which is smooth and polished, constitutes the parietal limit of the arachnoid cavity. It also forms certain septa, needless to specify, which intervene between the cerebrum and cerebellum and their respective hemispheres. At the foramina for the exit of nerves at the base of the skull the dura mater becomes continuous on the one hand with the pericranium, on the other with the nerve-sheaths. The *spinal dura mater*, which, like the cranial, is dense, thick, and inelastic, is prolonged in the form of a loose bag from the margins of the foramen magnum, to which it is adherent, to the first or second sacral vertebra, where, blending with the filum terminale of the cord, it is continued onwards therewith to the lower end of the sacral canal. The spinal dura mater is separated on all sides from the bony cavity in which it lies by fat and areolar tissue. Its internal surface is smooth and polished, and presents along either side a double series of orifices of which each contiguous pair gives exit to the anterior and posterior roots of one of the spinal nerves. The dura mater is continued on each nerve as a tubular prolongation, within which the ganglion of the posterior root is contained. It then blends with the sheath of the nerve, and becomes connected by fibrous processes with the margins of the intervertebral foramen.

The *arachnoid cavity* is usually regarded as a serous cavity. It occupies the interval between the dura mater on the one hand, and the general surface of the brain and cord on the other, being perfectly continuous throughout. Its outer limit is represented by the smooth inner aspect of the dura mater; its inner limit is formed by a delicate transparent membrane which lies loosely upon the surface of the central organs, never dipping into the sulci, and lying especially loosely upon the parts situated

at the base of the brain, and upon the spinal cord. The inner and outer aspects become continuous by means of tubular prolongations wherever nerves or vessels pass from the protective organs without to the central nervous organs within.

The *pia mater* is the vascular membrane which closely invests the outer surface of the brain and cord, following all its inequalities. It is continuous by its applied surface with the connective web and vascular network which pervade the substance of the subjacent organs; and the neurilemma of the nerves appears to be derived from it. The *pia mater* within the skull is delicate and highly vascular, dips to the bottom of all sulci, and accurately fits the complicated arrangement of processes and depressions which exist at the base of the brain. It dips also into the great transverse fissure of the brain, and into the somewhat similar fissure existing behind between the medulla oblongata and the cerebellum—forming in either situation a reduplication, the free margins of which are wrinkled and folded, and constitute the bodies known as the choroid plexuses. The *pia mater* of the cord is much thicker, denser, and less vascular than that of the brain, forms in front a duplicature which dips to the bottom of the anterior furrow, and behind a thin vertical septum which occupies the posterior furrow.

The interval which exists between the *pia mater* and the visceral lamina of the arachnoid is known as the *subarachnoid space*: it is crossed by numerous delicate fibrous bands, and in the spinal canal on either side by the ligamentum denticulatum, and behind by an incomplete vertical septum. It is the seat of the subarachnoid fluid, which constitutes the great bulk of the cerebro-spinal fluid.

2. *Ventricles of brain and cord*.—The existence of the ventricles of the brain and cord (excepting the fifth) as distinct cavities is due in some sense to the failure already referred to of the *pia mater* at the great transverse fissure of the brain and at the posterior part of the fourth ventricle to follow the various diverticula or involutions which take their origin in these situations. The system of ventricles comprises: the lateral ventricles, which are continuous with one another and with the third ventricle in the interval (into which the velum interpositum extends) between the fornix above and the optic thalami below; the third ventricle, which communicates by means of the iter with the fourth ventricle; the fourth ventricle; and the central canal of the cord which commences above at the calamus scriptorius or posterior extremity of the fourth ventricle. The nervous boundaries of the ventricles are covered with a delicate membrane which is continuous with the neuroglia or connective web permeating the substance of the subjacent organs, is identical in structure with it, and is furnished with an epithelium. The ventricles form a continuous system, and have no communication with other cavities or spaces, excepting with the subarachnoid space through Majendie's opening at the lower extremity of the fourth ventricle, and two other small openings, one on either side, close to the points of emergence of the glosso-pharyngeal nerves.

3. *Cerebral hemispheres*.—The cerebrum consists of two hemispheres, separated the one from the other above by the great longitudinal fissure, and united below mainly by means of the commissural fibres of the corpus callosum, by the fornix, and certain other structures which need not be specified. It is composed of white and grey matter, of which the one forms a comparatively thin lamina on the surface, while the other makes up the great bulk of its mass. The surface of the organ, and with it of course the grey matter, is arranged in folds or convolutions, separated by fissures or sulci, the more important of both of which present a tolerably definite and regular arrangement. The superficial grey matter is doubtless the seat of the intellectual and emotional functions, and the primary source of those various combined muscular actions which accompany and reveal their operation. The study of the convolutions is, therefore, a matter of interest, especially in connection with the localisation of function, on which subject important light has been thrown by modern pathology and recent experimental inquiries. We proceed to describe so much of the topography of the cerebral surface as bears directly on this subject.

a. *Fissures*.—The *fissure of Sylvius* (figs. 86 and 98, *d*) commences on the base of the brain at the locus perforatus anticus, and, separating the middle from the anterior cerebral lobe, passes directly outwards until it reaches the lateral aspect of the hemisphere. Here it divides into two branches: an anterior short branch, which proceeds upwards and forwards, and a posterior long branch, which courses nearly horizontally backwards upon the outer surface, dividing the temporo-sphenoidal lobe below from the parietal lobe above. The *fissure of Rolando*, or *sulcus centralis* (figs. 86 and 94, *c*), commencing above at the great longitudinal fissure a little behind the vertex, runs downwards and forwards over the outer surface of the hemisphere to near the point of bifurcation of the Sylvian fissure, separating the frontal lobe in front from the parietal lobe behind. The *inter-parietal fissure* (figs. 86 and 94, *e*), originating in the angle contained between the fissure of Rolando and the posterior Sylvian branch, passes irregularly backwards and towards the parieto-occipital fissure. The *parallel* or *first temporo-sphenoidal fissure* (fig. 86, *h*), running parallel to but below the posterior Sylvian branch, turns up behind its posterior extremity, and there loses itself in a group of convolutions, which are limited above and behind by the posterior part of the inter-parietal fissure, and are known by the name of the gyrus angularis or pli courbe. On the inner aspect of each hemisphere there are four fissures which call for special notice: the first is the *fronto-parietal* or *calloso-marginal* (fig. 87, *f*), which, commencing in front, runs backwards parallel with the corpus callosum, forming the upper limit of the gyrus fornicatus, until, having arrived near the posterior edge of the corpus callosum, it turns up to reach the upper margin of the hemisphere a little behind the upper termination of the fissure of Rolando; the second is the *vertical* or *parieto-occipital* (fig. 87, *g*), which separates the occipital from the parietal lobe, and, commencing above on a level with the posterior extremity of the parallel sulcus, runs downwards and forwards to unite at an acute angle

with (third) the *calcarine fissure* (fig. 87, *l*), which is nearly horizontal in position, and corresponds to the hippocampus minor; the last is the *hippocampal fissure* (fig. 87, *m*), which runs round the crus cerebri, and indicates the course of the hippocampus major.

FIG. 86.—Lateral view of brain, showing principal convolutions and fissures.

FIG. 87.—Inner surface of hemisphere, showing principal convolutions and fissures, and Ferrier's centres of touch (XIII), and of smell and taste (XIV).

The several letters in the above figures, and also in figures 93, 94, 96, 97, and 98, refer to the same parts.

Fissures:—*a*, superior frontal; *b*, inferior frontal; *c*, fissure of Rolando; *d*, fissure of Sylvius; *e*, inter-parietal; *f*, fronto-parietal; *g*, parieto-occipital; *h*, first temporo-sphenoidal; *i*, second ditto; *j*, third or inferior ditto; *k*, occipito-temporal; *l*, calcarine; *m*, hippocampal.

Convolutions:—*A*, superior or first frontal; *B*, second ditto; *C*, third ditto; *D*, ascending frontal, or anterior parietal; *E*, ascending parietal; *F*, superior parietal; *F1*, præcuneus; *G*, supra-marginal; *G1*, gyrus angularis, or pli courbe; *H*, first temporo-sphenoidal; *I*, second ditto; *J*, third ditto; *K*, fusiform lobule; *L*, lingual lobule; *M*, gyrus fornicatus; *M1*, gyrus hippocampi; *M2*, uncus gyri fornicati, or subiculum cornu Ammonis; *N*, cuneus.

The first frontal convolution (*A*), where it shows on the inner aspect of the hemisphere, is often called the marginal convolution; of which the hinder part, which is in relation with the ascending frontal and ascending parietal convolutions, is known as the paracentral lobule.

*b. Convolutions.*—In front of the fissure of Rolando, and following its course from below upwards, runs the *ascending frontal, or anterior parietal convolution* (figs. 86 and 94, *D*); and from the anterior aspect of this are given off in succession from above downwards the *first, second, and third*

*frontal convolutions* (figs. 86 and 94, A B C). The first of these runs parallel to the longitudinal fissure, and forms, indeed, the marginal convolution (fig. 87, A) of that fissure; the second follows the same course as the first, but lies external to it; and the third, still more external, by its posterior part forms the upper and anterior boundary of the anterior branch of the fissure of Sylvius, and by its anterior part separates the second convolution above from the external orbital convolution below. The third frontal convolution of the left side is also called *Broca's convolution*. The *orbital convolutions* occupy that portion of the under surface of the anterior cerebral lobe which lies upon the floor of the skull. Parallel to the ascending frontal convolution, and separated from it by the fissure of Rolando, courses the *ascending parietal convolution* (figs. 86 and 94, E E), from the posterior and outer margin of which two secondary convolutions, separated from one another by the inter-parietal sulcus, pass nearly directly backwards; the inner and upper one, the *superior parietal convolution* (figs. 86 and 94, F), forming the margin of the longitudinal fissure in this situation, and ending behind at the parieto-occipital fissure; the outer and lower one, or *gyrus supra-marginalis* (figs. 86 and 94, G), lying at its anterior extremity, mainly between the inter-parietal sulcus, and the posterior branch of the fissure of Sylvius, and further back between the inter-parietal sulcus and the posterior extremities of the Sylvian and first temporo-sphenoidal fissures. In the latter part of its course it is considerably curved, and receives the name of *gyrus angularis* or *pli courbe* (figs. 86 and 94, G<sub>1</sub>). There are three *temporo-sphenoidal convolutions* passing nearly horizontally backwards from the anterior part of the temporo-sphenoidal lobe; the first (fig. 86, H) is situated between the posterior branch of the Sylvian fissure above and the first temporo-sphenoidal fissure below; the second (fig. 86, I) lies below the first temporo-sphenoidal fissure; the third is lower down, but parallel to the others. At the bottom of the fissure of Sylvius, at its point of bifurcation, and concealed by the overlying convolutions, lies the *island of Reil*, the grey matter of which is in close anatomical relation in front with that of the posterior part of the third frontal convolution, behind with that of the first temporal. On the internal aspect of the hemisphere, amongst other convolutions, may be observed the *gyrus fornicatus* (fig. 87, M), which, commencing in front beneath the genu of the corpus callosum, runs backwards over this body, between it and the calloso-marginal fissure, then turns round its posterior extremity, being continued downwards and forwards under the name of the *gyrus hippocampi*, or *uncinate convolution* (figs. 87 and 98, M<sub>1</sub>), first between the hippocampal and calcarine fissures, and thence nearly horizontally forwards until it reaches the internal extremity of the fissure of Sylvius, where it forms the *uncus gyri fornicati*, or *subiculum cornu Ammonis* (figs. 87 and 98, M<sub>11</sub>). For an account of the remaining convolutions, to some of which we may subsequently allude incidentally, we must refer to anatomical works.

In connection with the subject of the convolutions it may be observed that M. Betz has shown that the surface of the cerebrum may be divided

by microscopic peculiarities into two regions, of which the anterior, limited by and including the ascending parietal convolution, is characterised by containing, in greater or less abundance, giant-cells resembling those of the anterior cornua of the spinal cord, the posterior by an almost total absence of such cells.

4. *Ganglia at base of brain*.—Excepting the fibres which go to the formation of the corpus callosum and fornix, and certain other commissures, which need not be enumerated, all the nerve-fibres from the grey matter of the convolutions converge to the region of the group of ganglia situated at the base of the brain, namely, the corpora striata and the optic thalami, together with the corpora geniculata and corpora quadrigemina, and are thence continued (directly or indirectly) either through the superior cerebellar peduncles to the cerebellum or along the crura cerebri to the medulla oblongata.

Each *striated body* comprises three nuclei, separated from one another by white fibres. The first of these is the *caudate nucleus*, and is that portion of the body which is visible in the lateral ventricle. The second is the *lenticular nucleus*, which is placed in part external to and below the caudate nucleus, in part external to and below the optic thalamus: being separated from these bodies by a layer of white fibres, which forms the internal capsule, and on the outer side from the grey matter of the island of Reil by a similar white lamina, which is known as the external capsule. Imbedded in this last is the third or *tæniæform nucleus* or *claustrum*, which forms an exceedingly thin plate. The cerebral fibres which enter these nuclei and occupy the intervals between them come from all parts of the cerebral surface, but mainly from the anterior half; and those which emerge from them below pass mainly downwards and backwards to form the under portion or *crust* of the corresponding cerebral peduncle, within which they become connected with an additional ganglion of the same system, namely, the *locus niger*. The further destination of the crust is twofold: it sinks into the anterior and upper edge of the pons, and there divides into two portions; of which one, according to Meynert, crosses among the anterior fibres of the pons, and passes with these to the opposite half of the cerebellum, thus decussating with its fellow; while the other emerges from the posterior border of the pons as the anterior pyramid, which also decussates with its fellow, and passes mainly into the lateral column of the opposite side of the cord.

It may be convenient to add a more minute account of the arrangement and connections of the strands of fibres contained in the crust. Nearly one half of them, occupying a median position, are derived from the ascending frontal and ascending parietal convolutions, and certain adjoining motor areas, and below form the anterior pyramid of the same side. To the inner side of this strand lies another, which comes from all that portion of the frontal lobe lying in front of the convolutions above specified. A third strand, situated to the outer side of the pyramidal fibres, appears to be derived from the occipital and temporal lobes, and to reach the crista behind and below the basal ganglia, and thus

Posterior frontal section.

FIG. 90.  
Anterior parietal section.

FIG. 91.  
Posterior parietal section.

The Roman capitals in the above figures have the same meaning as those in figures 86 and 87. The verbal Greek letters in the above figures relate to identical parts.

- a. Island of Reil.
- β. Corpus callosum.
- γ. Caudate nucleus.
- δ. Lenticular nucleus.

- ε. Tæniæform nucleus.
- ζ. Optic thalamus.
- η. Internal capsule.
- θ. External capsule.

From the Thèse Inaugurale of M. Pitres, 'Recherches sur les lésions du centre ovale des hémisphères cérébraux, étudiées au point de vue des localisations cérébrales.' Paris, 1877.

without passing through the internal capsule. A fourth group of fibres, which lies between the other three and the locus niger, is believed to come from the corpus striatum. The last three strands of fibres all lose themselves in the grey matter of the pons, and appear to become there connected with the opposite half of the cerebellum. They have not been traced into the medulla.

The *optic thalami*, *corpora geniculata*, and *corpora quadrigemina* also derive fibres from nearly all parts of the cerebral surface, though mainly probably from the posterior and lateral portions; and, resting by their under surface upon the cerebral peduncles, are more or less directly continuous with their upper half, or the *tegmentum*. This, which includes within it the *red nucleus*, divides, like the crust, into two portions. One of these continues backwards as the *processus e cerebello ad testes* and *valve of Vieussens* to form the superior peduncles of the cerebellum; and the fibres which constitute it for the most part decussate anteriorly to the posterior limit of the testes, and so reach the opposite sides of the cerebellum. The other continues downwards in the substance of the pons and on the floor of the fourth ventricle, to become continuous mainly with the sensory tracts of the medulla oblongata and cord.

5. *Cerebellum and its peduncles*.—So little is known comparatively of the specific functions of different parts of the cerebellum that it is needless to consider here either its general form and arrangement or the names which have been given to its separate lobes and lobules. It may, however, be pointed out that, in addition to its superficial grey investment, it contains imbedded in its white medulla in the first place two ganglia (one on either side), the *corpora dentata*, and in the next place two other grey nuclei, the *roof nuclei* of Stilling, which lie below the central lobule of the superior vermiform process.

The cerebellum presents three pairs of peduncles or groups of white fibres, of which one comes from the cerebrum, one from the medulla oblongata, and the other is mainly transversely commissural. The first pair or the *superior peduncles* come almost exclusively from the tegmentum of the cerebral peduncles, comprise the *processus e cerebello ad testes* with the intermediate valve of Vieussens, and pass into the corpora dentata and thence to the convolutions. The second pair or the *middle peduncles* are constituted mainly by the transverse fibres which form the great bulk of the pons Varolii, but comprise the cerebellar fibres derived from the crust of the cerebral peduncles; of these the more internal pass into the roof nuclei, but the outermost, accompanied by the restiform bodies, reach the surface of the cerebellum without the intermediation of either of these ganglia. The third pair, or the *inferior peduncles*, are the restiform bodies.

It will thus be seen that the most direct, if not the only, communication between the hemispheres of the cerebrum and those of the cerebellum is effected by means of fibres which, taking their origin in the cerebral ganglia, pass backwards and lose themselves probably in the ganglia imbedded in the white substance of the cerebellum; that of these some are derived from the crust, some from the tegmentum of the crura cerebri

and that all, according to Meynert, decussate in the course of their passage. It will also be gathered that both the cerebrum and the cerebellum send down strands of fibres to take part in the formation of the medulla oblongata. Those from the brain are continued from both layers of the crura cerebri; those from the cerebellum are the restiform bodies.

6. *Spinal cord*.—Before speaking further of the medulla oblongata it will be well to describe the spinal cord. This, which extends, in the adult, from the foramen magnum above to the lower part of the first lumbar vertebra below, presents an anterior and a posterior median fissure, and on either side two lateral furrows, which correspond to the successive points of emergence of the anterior and posterior roots. It is thus divided superficially, on each side, into posterior, lateral, and anterior columns. But, in addition to these, a slender median column, most obvious in the

FIG. 92. —Diagrammatic sections of the spinal cord  $\times 2$ .

upper part of the cord, may be observed, running along the edge of the posterior median fissure. On transverse section the grey matter of the cord will be found to occupy its central part, the white its periphery. The grey matter is arranged in the form of two lateral crescents, placed back to back, and united with one another in the middle by a transverse commissure, which crosses the narrow interval between the bottoms of the anterior and posterior fissures, and contains within it the ventricle of the cord. The posterior limb of each crescent constitutes the posterior horn of grey matter, the anterior limb the anterior horn. In the latter are situated distinct groups of large multipolar cells, which appear to be the nuclei of origin of the anterior or motor nerves; and from it the root of each nerve passes forwards through the substance of the white matter in several parallel bands. The posterior horn is tipped by the gelatinous

substance of Rolando, from the whole transverse extent of which the fibres of each posterior root escape in wavy bands, some undulating through the substance of the adjoining posterior column, previous to their appearance at the surface of the cord. At the root of the posterior cornu, on its outer side, is the group of cells which indicates the longitudinal tract to which Lockhart Clarke has given the name of *tractus intermedio-lateralis*; and in almost the corresponding situation, on its inner side, may be seen the sectional surface of the tract of cells which constitutes Clarke's *posterior vesicular column*. Less on anatomical than on physiological and pathological evidence, the white matter of the cord admits of division into several regions which are functionally distinct from one another. As regards the posterior columns, these, as has already been pointed out, may be divided into two parts, namely, the *posterior median columns*, or fasciculi of Goll, situated on either side of the posterior median fissure, and the *posterior external columns* (*posterior root-zones* or *Burdach's columns*), lying between these and the posterior horns of grey matter, and nerves springing from them. Each lateral column presents on transverse section a wedge of white matter, situated almost entirely behind the ventricle and in close relation with the posterior grey horn. It represents the direct continuation downwards of nearly the whole of the opposite anterior pyramid. This may be termed the *crossed pyramidal tract*. It is separated from the outer surface of the cord by a lamina of white matter connected with the cerebellum, and called the *direct cerebellar tract*. On either side of the anterior median fissure is a thin tract of white matter which descends directly from the anterior pyramid of its own side. This is termed the *fasciculus of Türck*, or the *direct pyramidal tract*. The white matter around the anterior cornua, exclusive of the crossed pyramidal tracts and the columns of Türck, constitutes the anterior root-zones. And lastly, Dr. Gowers, in a case of cord crushed in its lower part, found symmetrical areas of slight ascending degeneration in the anterior part of the lateral columns in front of the pyramidal tracts. These he could not trace far up the cord. But Dr. Hadden discovered in the upper part of the cervical cord, from a case of which the history was unknown, symmetrical tracts of degeneration occupying almost exactly the same relative positions as those of Dr. Gowers, but separated from the surface by a thin layer of healthy white matter. They are doubtless parts of the same tracts, and there is good reason to believe, partly from the fact that in one case at any rate they were the seat of ascending degenerative changes, that they represent sensory routes. The grey matter varies in bulk in different parts of cord, and is especially abundant in the cervical and lumbar enlargements, but the superficial white matter increases absolutely in quantity from below upwards.

7. *Medulla oblongata*.—At the upper part of the cord, where it merges in the medulla oblongata, considerable changes are presented in the distribution of its parts. These changes become more and more remarkable as we proceed from the lower to the upper part of the medulla oblongata, and are complicated by the appearance of additional grey nuclei. The

posterior fissure opens out and blends with the ventricle of the cord ; the posterior pyramids are divaricated, forming between them the calamus scriptorius ; and the remainder of the posterior columns, now constituting the restiform bodies, passes upwards and outwards to form the inferior peduncles of the cerebellum ; in front of these is gradually developed, on either side, a grey column, due to the altered position of the gelatinous substance of Rolando ; still further forwards we see the seeming blending of each lateral column with its olivary body, and in front the anterior columns, apparently continued upwards into the anterior pyramids. The arrangement of parts here is exceedingly complicated ; but it may be stated generally : that the bulk of each posterior column of the cord, together with the direct cerebellar tracts of the same side, passes upwards in the restiform body to the cerebellum ; and that, according to Meynert, it has in its passage upwards a direct connection with the olivary body, and that in this region decussation of the tracts of opposite sides takes place, so that the relation between the cord and cerebellum becomes crossed ; that the greater part of the white substance of each antero-lateral column decussates with the corresponding part of the opposite side at the lower extremity of the anterior pyramid ; and that each pyramid is hence constituted mainly by the continuation upwards of the medullary matter of the opposite side of the cord to that on which it is itself situated, and then, passing through the substance of the pons Varolii, forms in front of it the larger bulk of the crust of the corresponding cerebral peduncle ; and, lastly, that some portion of the fibres of the lateral columns, and most of the opened-out grey matter of the cord, pass upwards along the floor of the fourth ventricle and back of the pons Varolii, partly to form the tegmentum, partly to become associated with the grey matter of the iter and third ventricle.

8. *Cerebro-spinal nerves*.—The cerebro-spinal nerves, with only two exceptions, originate in the grey matter of the spinal cord, or its continuations, in the medulla oblongata, along the floor of the fourth ventricle, and around the iter. They are of two kinds, motor and sensory. The motor spinal nerves have their immediate origin in the groups of large cells contained in the anterior cornua, and emerge at the surface of the cord in the furrows separating the anterior from the lateral columns ; the sensory nerves originate apparently in the posterior cornua, and make their appearance superficially in the groove which divides the lateral from the posterior columns.

The cerebral nerves, in the main, arise according to their properties in the upward continuations of the motor and sensory tracts of the grey matter of the cord ; in other words, the motor nerves spring from the upward continuation of that portion of grey matter which is anterior to the spinal ventricle, the sensory nerves from the upward continuation of the portion behind it. But these tracts, as has been shown, become modified in their relative positions in the medulla oblongata and floor of the fourth ventricle : the motor tract gets superficial on either side of the median line in the course of the fasciculi teretes ; the sensory tract, on the other hand, split

into two halves, continues upwards on either side of the motor tract, occupying each lateral half of the floor of the ventricle, spreading out on either side along the inner aspect of the cerebellar peduncles towards the cerebellum, and at the anterior point of the fourth ventricle rising up and coalescing again, as in the cord, over the iter or tubular continuation of the ventricle.

The motor nerves, in their order from behind forwards, are the spinal accessory, the hypoglossal, the portio dura, the abducens or sixth, the motor branch of the fifth, the fourth, and the third. The upper part of the spinal accessory arises from a nucleus situated in the lower part of the medulla oblongata, a little outside the central canal, and concealed by the posterior pyramid; and it becomes superficial as the lowermost member of the eighth nerve at the lateral aspect of the medulla below the level of the olivary body. The nucleus of the ninth, or hypoglossal nerve, commences below in front of the spinal canal, in contact with the spinal accessory nucleus, and extends for a short distance along the floor of the fourth ventricle in the neighbourhood of the calamus scriptorius. Its superficial origin is between the olivary body and the anterior pyramid. The common nucleus of the portio dura of the seventh nerve and abducens is situated just in front of the hypoglossal nucleus. The former nerve becomes superficial at the posterior margin of the pons, between the middle and inferior peduncles of the cerebellum; the latter in the groove between the anterior pyramid and the pons. The nucleus of the motor root of the fifth nerve is situated within the fasciculus teres, a little above, in front of, and external to that of the portio dura; the nerve becomes superficial by penetrating the lateral portion of the pons. The third and fourth pairs arise in common from a pair of nuclei, situated side by side in the floor of the iter. The fourth nerves encircle the iter in their course, and then winding round the outer side of the crura cerebri reach the base of the brain; each third nerve penetrates the subjacent locus niger, and makes its appearance on the inner side of the crus.

The sensory nerves, in their order from behind forwards, are the vagus, the glosso-pharyngeal, the auditory, and the sensory portion of the fifth; to which may be added the optic and the olfactory. The nucleus of the vagus, connected with that of the spinal accessory below, appears on the floor of the fourth ventricle just above the calamus, and external to the hypoglossal nucleus. Above, it appears to sink beneath the auditory nucleus. The glosso-pharyngeal nucleus, which is partly continuous with that of the par vagum, but higher up, is wholly concealed by the auditory nucleus, with which it is in some measure blended. These two nerves become superficial along the posterior border of the olive. The auditory nucleus is of large size; it involves the upward continuation of the grey matter of Rolando, and, in part, the posterior pyramid and restiform body. It occupies the floor of the ventricle external to the fasciculus teres, and its outer part turns backwards with the restiform body to reach the cerebellum, some portion of it becoming connected with the dentate nucleus, some stretching across the roof of the ventricle to join its fellow.

The nerve-fibres arising from this nucleus, taking various routes, combine to form the portio mollis, which has its superficial origin at the posterior margin of the pons, between the superior and middle cerebellar peduncles. The nucleus of the sensory portion of the fifth is, like the auditory, largely developed out of the upward continuation of the grey tubercle of Rolando, and also from that of the root of the posterior horn. It is situated in advance of the nucleus of the portio mollis (with which, indeed, it is, to some extent, connected behind), and extending upwards to the fossa, where the fillet meets the anterior fibres of the pons, arches backwards with the rest of the continuation of the grey matter from the cord towards the side and roof of the anterior part of the fourth ventricle and of the adjoining part of the iter. The superficial origin of the nerve is to the anterior and outer part of the pons Varolii. The optic nerves interlace in the chiasma, and thence each optic tract winds round the corresponding crus cerebri to reach the posterior portion of the optic thalamus, the corpora geniculata, and the corpora quadrigemina, of the corresponding side, which therefore may be regarded as its nuclei, or at all events as containing its nuclei; but, further, the optic tract in its whole extent is intimately connected structurally with the crus cerebri, and the chiasma with the grey matter lining the third ventricle. The olfactory nerve is really, as comparative anatomy has long shown, a lobe of nervous substance. It is formed of grey and white matter, and contains, according to Meynert, a central ventricle continuous with those of the cerebrum, which, however, according to Struthers, is absent in the adult; its so-called roots are connected respectively with the anterior and posterior extremities of the gyrus fornicatus, and some of the white fibres connected with it have been traced into the anterior commissure. It is an important fact that the fibres of the anterior commissure are connected with the occipital and temporo-sphenoidal lobes only, and that hence the olfactory nerves, and it may be added, from their connection with the optic thalami and associated ganglia, the optic nerves, are both intimately connected with that portion of the brain with which, through the intermediation of the same ganglia, the rest of the sensory nerves are connected.

9. *Résumé of the relations of the different parts of the central nervous system.*—The anterior portion of the surface of the brain (all that in front of the fissures of Rolando, together with the ascending parietal convolutions behind those fissures, and certain other convolutions connected therewith) appears on sufficiently good grounds to be regarded as the supreme organ of the cerebro-motor processes or impulses; and, indeed, as will presently be pointed out, pathological and experimental investigations have demonstrated that certain definite regions of this area are connected with certain special groups of combined movements. From all this extent of surface radiating fibres converge to certain parts at the base of the brain, namely, the caudate and lenticular nuclei of the corpora striata and the white matter (the internal capsules) which lies between these bodies and the optic thalami. Of these radiating fibres some pass without interruption through the internal capsules, while others probably

enter the nuclei of the corpora striata. Below these nuclei, the fibres passing uninterruptedly through the internal capsules, together with others given off from the under surface of the corpora striata, form the crustæ of the crura cerebri, which, continued downwards through the pons Varolii, emerge from its posterior and lower border in the form of the anterior pyramids of the medulla oblongata. Hitherto the fibres derived from each cerebral hemisphere have travelled downwards and backwards on the corresponding side of the body; at the lower part of the anterior pyramids, however, decussation takes place, and the fibres of the anterior pyramid of one side are continued downwards, mainly along the anterior and lateral white columns of the opposite side of the cord. But, in addition to the corpora striata, with which bodies all the fibres passing from the cerebro-motor region of the brain have, in their passage downwards, a more or less intimate connection, there are, imbedded as it were in each lateral motor tract, a series of subordinate motor centres or nuclei, succeeding one another in close succession from the floor of the iter above to the termination of the cord below, each one of which gives origin to a motor nerve or to a certain number of fibres going to the constitution of a motor nerve.

It follows generally from the above account that complex motor impulses, originating in the hemispheres of the brain, are conveyed along the radiating fibres to the corpora striata or other accumulations of grey matter, through the agency of which bodies, resolved as it were into their simplest elements, they are transmitted to the several subordinate cerebral and spinal nuclei which immediately govern the movements of those muscles, which in combination effect intended results. It follows generally also that impulses originating in one cerebral hemisphere act through the region of the corpus striatum of the same side upon the spinal nuclei of the opposite side of the body, and hence upon the muscles of the opposite side of the body. The same holds good of those motor nerves whose origins are situated above the decussation of the pyramids. There are, however, certain exceptions to these statements, due doubtless to the fact of the intimate connection by means of commissural fibres between the two hemispheres of the brain, and especially to the similar connection which subsists between the corresponding motor nuclei of opposite sides along the motor tracts. These exceptions are presented especially by the motor nerves of the eyes, and by the nerves concerned in phonation, respiration, and other acts in which the corresponding muscles of opposite sides of the body habitually act in unison or concert. Further, it must not be forgotten that every subordinate motor centre has independent motor powers, which, if it retain its connection with its correlated afferent centre, are capable of being brought into action by reflex stimulation: that, if the cerebrum be removed, or its functions in abeyance, combined movements, to all appearance voluntary, may be effected through the immediate agency of the corpora striata; that if the spinal centres be cut off from their connection with the higher centres, these also are capable of inducing reflex movements; and that under various conditions of health

and disease the independent action of these various subordinate centres is a fact of more or less importance.

The afferent or sensory nerves, which near their entrance into the spinal marrow are furnished with ganglia, penetrate into the posterior cornua, and thus become connected with that portion of grey matter lying behind the central canal which constitutes the sensory region of the spinal cord. This sensory region occupies the whole length of the cord, and at the medulla oblongata becomes split longitudinally from before backwards both halves passing upwards, one on either side of the now superficial motor nuclei of the medulla oblongata, to form the tegmenta and to become connected with the optic thalami, corpora geniculata, and corpora quadrigemina, and thus with the nuclei of origin of the optic nerves. From these ganglia radiating fibres proceed mainly to the grey cortex of the posterior portions of the cerebrum or to the true sensorium. Thus it appears that the posterior part of the cerebral surface has some such relation with the sensory functions as the anterior has with the motor functions, and the optic thalami and ganglia behind them some such connection with the same system as the corpora striata have with the motorial. And further, it seems probable (judging at all events by the analogies afforded by the organs of seeing and hearing) that complicated external impressions become analysed or disentangled, as it were, or reduced to their simplest elements by the organs which first receive them; to become again blended into a whole, so to speak, in their onward progress to the sensorium. Both experiment and pathology have shown conclusively that the sensory tracts decussate equally with the motor; and that the cerebral hemisphere and optic thalamus of one side are in direct relation with the sensory tract and nerves of the opposite half of the medulla oblongata and spinal cord. The decussation does not, however, take place in the pyramids or at any one spot; but each sensory nerve immediately after its entry into the grey matter of the cord decussates with its fellow of the opposite side, and its fibres of communication with the optic thalamus continue thenceforward to pass upwards on the same side as that body.

The relations of the cerebellum with the motor and sensory tracts as they traverse the base of the encephalon have already been considered, and its connection with the posterior columns of the cord through the intervention of the restiform bodies has also been pointed out. It is further established that the posterior columns of the cord are in no sense the conductors of ordinary sensory impressions, as from their position was formerly supposed, but that whether afferent or merely commissural they are mainly subservient to the co-ordinating functions.

It is important to bear in mind: that at the base of the brain, and especially in the situation of the pons Varolii and medulla oblongata, the sensory and motor tracts of both sides become to some extent intermingled, that the nuclei of origin of many nerves of the highest interest and importance are crowded together into a very small space, and that hence disease affecting these parts is liable to be attended with complex, aggravated, and

it may be added striking features ; and that as regards the cord the sensory tracts, although probably in part occupying the lateral white columns, are mainly imbedded in its interior, while nearly all the white matter which forms its peripheral portion as well as the anterior cornua belong to the motor system, and that hence the sensory columns are specially protected from the influence of pressure or other injurious influences operating from without.

10. *Localisation of function.*—*a.* Pathological observation and recent experimental researches have combined to prove : that certain definite areas of the grey surface of the cerebral hemispheres are the seats of special endowments ; and that their stimulation is attended with certain specific consequences, for the most part revealed by definite groups of movements, their destruction by equally specific consequences of an opposite or paralytic kind. It need scarcely be said that experimental investigation has been conducted almost exclusively on the lower animals, and that hence the determination of the areas above referred to in relation to the human brain can only be regarded as approximative. The positions assigned to these areas or centres by Dr. Ferrier are shown in Figs. 93, 94, and 87.<sup>1</sup>

It will there be seen : that the centre (v) for movements of the lips and tongue occupies the posterior part of the third frontal and the lower

FIG. 93.—Lateral view of brain, showing Ferrier's centres of movements.

The Roman numbers in the above figure, and in Figs. 94 and 87, refer to Ferrier's centres.

i. lateral movements of head and eyes, with elevation of eyelids and dilatation of pupils ; ii. extension of arm and hand ; iii. complex movements of arm and leg, as in climbing, swimming, &c. ; iv. movements of leg and foot, as in locomotion ; v. movements of lips and tongue, as in articulation ; vi. depression of angle of mouth ; vii. elevation of angle of mouth ; viii. supination of hand and flexion of forearm ; ix. centre of platysma—retraction of angle of mouth ; x. movements of hand and wrist ; xi. centre of vision ; xii. centre of hearing ; xiii. centre of touch ; xiv. centre of smell and taste.

ascending frontal, encroaching, however, on the neighbouring ascending parietal and on the first frontal, is situated the centre (iii) for complex movements of the arm and leg, as in climbing, swimming, and the like immediately in front, upon the first frontal, the centre (ii) for extension

part of the ascending frontal convolutions ; and that in immediate relation with this are the centres, (vi) for the depression of the angle of the mouth, (vii) for its elevation (both seated in the ascending frontal), and (ix) for its retraction with contraction of the platysma (occupying the lower part of the ascending parietal). At the upper part of the

<sup>1</sup> For much of what follows see Dr. Ferrier on the 'Functions of the Brain.'

of the hand and arm; just behind it, and occupying partly the upper extremity of the ascending parietal, and partly the superior parietal, the centre (iv) for movements of the leg and foot, as in locomotion; and adjoining it, at the upper part of the ascending frontal, the centre (viii) for supination of the hand and flexion of the forearm. The centres marked (x), occupying the greater part of the ascending parietal, are connected with movements of the hand and wrist; and that marked (i), seated in the first and second frontal convolutions, is correlated with lateral movements of the head and eyes to the opposite side, elevation of eyelids, dilatation of pupils, and generally the look of surprise. Horsley and Schäfer have shown by experiment that that portion of the marginal convolution (Figs. 87, 94 A A) which is in relation with the upper extremity of the ascending frontal convolution is the centre for the movements of the trunk and of the muscles acting from the trunk upon the limbs. In order, however, to produce complete paralysis, it seems to be necessary that both marginal lobes be extirpated. It will be observed that all the above centres are included in that area of the surface of the brain which is in special relation through the corpus striatum with the motor tract, and which, according to M. Betz, contains giant-cells resembling those of the anterior cornua of the cord.

Below and behind the inter-parietal and Sylvian fissures is a series of centres which, though associated like the others with more or less definite movements, are really sensory centres; the movements due to their stimulation being excited reflectorily through the motor centres, and their destruction being unattended with loss of muscular power. The first of these (represented by a group of circles numbered xi), which occupies the whole extent of the supramarginal convolution and *pli courbe*, is the centre of vision. Its destruction causes temporary

blindness of the opposite eye; the destruction of both causes permanent and absolute blindness of both eyes. Its irritation appears to evoke subjective visual phenomena in the opposite eye, with turning of the eyeballs, and frequently of the head, towards that side, and contraction of the pupils. The second of these (xii) corresponds to nearly the whole of the

FIG. 94. Upper aspect of brain, showing principal convolutions and fissures; and on the left side Ferrier's centres of movements, and on the right the arterial area.

first temporo-sphenoidal convolution. It has a similar relation to hearing that the last has to seeing. Destruction of this part involves absolute loss of hearing on the opposite side; irritation causes sudden pricking of the opposite ear, and turning of the head and eyes in the same direction, with opening of the eyes and dilatation of the pupils. The third (fig. 87, XIII), situated in the hippocampal region, appears to be the centre for tactile sensation. Its destruction is attended with hemianæsthesia; its irritation with movements indicative of pain or uneasiness in the opposite side of the body. The last (fig. 87, XIV) is the centre of smell; intimately associated with which, though as yet impossible of exact localisation, is the centre of taste. Irritation of the centre of smell induces torsion of the upper lip and partial closure of the nostril on the same side as the centre; its destruction abolishes the sense of smell in the same nostril. Irritation of the part of the surface of the brain concerned in taste provokes movements of the lips, tongue, and cheeks; its destruction involves the abolition of the gustatory sense in the opposite side of the mouth. These sensory centres occupy that part of the brain which is in special relation with the sensory tract, and which, as M. Betz shows, presents an almost total absence of giant-cells. There are certain parts of the cerebral surface the effects of irritation of which are negative. These are especially the gyri fornicati, the islands of Reil, and the anterior parts of the frontal lobes, including the parts which overlie the orbits.

We proceed to supplement the foregoing statement by some of the facts ascertained by clinical and pathological experience. It does not seem to have been yet proved that, in the case of the human being, there is any centre in the situation of area (1) for the movement of the head and eyes. It appears, however, to be certain that the ascending frontal and ascending parietal convolutions, the paracentral lobule, and the adjoining portions of the first and third frontal and superior parietal convolutions, comprise centres of movement of the face and tongue, and upper and lower extremities, for the most part similarly arranged to the corresponding centres existing in the lower animals; and that the centre for the movement of the lips and tongue occupies the posterior part of the third frontal, and adjoining part of the ascending frontal convolutions, which region on the left side is the motor centre of speech. The sensory centres, so far as has been ascertained, are all comprised in the temporo-sphenoidal and occipital lobes and in the supra-marginal and angular gyri of the parietal lobe. The seat of the centre of common sensation has not been accurately determined. It occupies in part, no doubt, the region ascribed to it by Ferrier, but there is reason to believe, as Dr. Gowers argues, that it is of much larger extent, and involves even more or less of the outer aspect of the hemisphere. The centre of smell appears to be at the anterior extremity of the uncinatè convolution; and, as stated above, disease of this centre influences the nostril and lips on the same side. Nevertheless there is reason to believe, from clinical facts, that the fibres of the olfactory nerves do cross to some extent, so that the nerve of one side becomes connected in a greater or less degree with the opposite hemisphere.

The centre of vision is situated partly, as Ferrier has demonstrated, in the angular gyrus; but there is abundant pathological evidence to show that the occipital lobe forms also a portion of the visual area. For while destructive lesions of the angular gyrus cause amblyopia of the opposite eye, with more or less contraction of the field of vision, a similar lesion of the occipital lobe causes hemianopia of both eyes on the same side as itself.

It is a matter of considerable interest and importance that, while for the most part the motor and sensory centres of one side are specially connected with movements and sensations on the opposite side of the body, they have generally, though in a less degree, some influence over the corresponding phenomena on the same side; and that hence, when, owing to permanent destructive lesions of one side of the brain, especially in early life, paralysis or anæsthesia in the domain of certain nerves or groups of nerves takes place, there is a tendency in the course of time towards the restoration, in a greater or less degree, of the lost function. Generally, however, motor paralysis of parts whose movements are wholly independent of those of the corresponding parts on the opposite side tends to be permanent. And it may be pointed out that while crossed amblyopia due to lesion of the opposite angular gyrus, conforms to the usual rule and tends to recovery, the double hemianopia due to disease of one occipital lobe is usually persistent.

*b.* As might naturally be supposed, from its relations to the hemisphere above and to the medulla oblongata and cord below, destruction of the corpus striatum is attended with paralysis of voluntary motion of the opposite side of the body, excepting in so far as this is obviated by the intimate connections subsisting between those collateral spinal nuclei supplying opposite muscles which habitually act in unison. Irritation of this ganglion causes spasmodic contraction of the muscles on the opposite side of the body.

*c.* It seems clear that the optic thalamus has the same relation to sensation, including tactile sensation, sight, hearing, and taste (but possibly not smell), that the corpus striatum has to motion. It is stated that irritation of this body is unattended with motor manifestations, while its destruction involves hemianæsthesia of the opposite side of the body, including loss or impairment of taste and hearing, impairment of smell, due to anæsthesia in the domain of the fifth nerve, and blindness. Yet in one case, in which there was partial destruction of both thalami, the main symptoms were paresis with tremors, followed by rigidity. Dr. Hughlings Jackson records a case of destruction of the optic thalamus by disease, in which, together with the phenomena above enumerated, there was loss of sight in the half of each retina on the same side as the lesion. It has been maintained by many physiologists that the optic thalamus has not the connection with sensation here assigned to it, but that the posterior part of the internal capsule is the direct channel for the transmission of peripheral sensory impressions to the surface of the brain. There is no doubt that this is so far true that destruction of this part causes, like destruction of the thalamus, opposite hemianæsthesia.

*d.* Whatever other functions may belong to the cerebellum, at any rate this portion of the encephalon appears beyond all doubt to be the supreme centre for the regulation of the 'various muscular adjustments necessary to maintain the equilibrium of the body.' But the maintenance of equilibrium demands not only a central organ, but a sensory or afferent mechanism by which the central organ may be kept informed of the condition of the body in relation to equilibrium, and an efferent or motor mechanism by means of which muscular adjustments may be effected. The former of these are the organs of common sensation, the eyes, and, more important than all, the semi-circular canals with their afferent nerves; the latter are the motor nerves and voluntary muscles.

Experimental lesions of the cerebellum induce disorders of equilibrium, but never impairment of sensation, or actual loss of voluntary muscular power. Without entering into any physiological explanation of the phenomena, we may briefly state that experimental evidence proves that destructive lesions of the anterior part of the middle lobe cause a tendency to fall forwards, of the posterior part of the middle lobe a tendency to fall backwards, of the right lobe a tendency to turn to the left (in the case of one of the lower animals, therefore, or of a person lying down, to roll from left to right, or towards the injured side), and of the left lobe a tendency to turn to the right; and that precisely converse tendencies result from irritation of the same parts. Attending these movements there is spasmodic contraction of the muscles of that side of the body towards which twisting occurs; and when the lateral lobes are affected the twist commences with spasmodic torsion of the head and neck. Usually also there is conjugate deviation of the eyes to the right, left, upwards, or downwards, in accordance with the direction of the general bodily movements, or more or less nystagmus. Lesions of the structures connected with the cerebellum are also attended with disturbance of equilibrium; division or destruction of the middle peduncle of the cerebellum on either side causing the same symptoms as destructive lesions of the corresponding cerebellar lobe; and irritation and injury of the corpora quadrigemina equally inducing inco-ordination of movement. Affections of the semicircular canals produce the same consequences as regards equilibrium as affections of the cerebellum: affections of the superior vertical canals being equivalent to affections of the anterior part of the middle lobe; affections of the posterior vertical canals to those of the posterior part of the middle lobe; and affections of the horizontal canals to those of the corresponding lateral lobes.

*e.* The corpora quadrigemina are through the corpora geniculata brought into immediate relation with the optic tracts, and, indeed, there is no doubt that these bodies are the subordinate centres of vision, and have reflex connections with the motor nerves of the eyes. In the lower animals destruction of one optic lobe causes blindness of the opposite eye and more or less immobility of the pupil; irritation induces sudden starting backwards of the animal as if in alarm, turning of the eyes and head to the opposite side, dilatation of the pupils, and spasmodic con-

traction of the facial muscles with trismus and opisthotonos. It is important to note that the pupils are completely paralysed only when the destruction of these bodies is bilateral; and that when irritation causes dilatation of the opposite pupil, dilatation of the pupil of the sound side speedily follows. In man destruction of one of the anterior tubercles of the corpora quadrigemina appears to cause hemianæsthesia in both eyes on the same side as the lesion. There are good reasons for believing that the testes are particularly connected with some forms of emotional expression. We have already referred to the relation of the corpora quadrigemina to equilibrium. In one case under our care, in which these bodies appeared to be wholly destroyed by a tumour arising in their substance, there was paresis of all the ocular muscles with ptosis and exophthalmos, and tremulous movements of the head and arms; but no affection of the internal muscles of the eyes; and the patient could see.

*f.* From the anatomical facts which have been detailed it is obvious that the medulla oblongata, including all that region from which the cerebral nerves arise, is the chief centre of many important functions which are more or less essential to the maintenance of life. It is clearly established, indeed, that even in warm-blooded animals all the centres above the medulla oblongata may be removed without destroying life; and that with the medulla oblongata remaining respiration and deglutition are still capable of performance. The medulla is in fact the co-ordinating centre of the respiratory acts, of phonation, of articulation, of facial expression, and of the acts of sucking and deglutition. Moreover, it is the centre of inhibition and acceleration of the action of the heart, and the centre of innervation of the blood-vessels. The co-ordinating centre of respiration is placed by Flourens in the angle of the calamus scriptorius.

*g.* As regards the cord all that we need add to statements already made is: that like the medulla it is a centre, though subordinate centre, of reflex action; that cut off from its connection with the parts above it is still capable, through its afferent and efferent connections, of producing co-ordinated movements; that under such circumstances irritation of the ends of sensory nerves generally causes reflex movements of the part with which the irritated nerves are in relation; that if the irritation be extreme or the cord unnaturally irritable the influence, instead of remaining limited, becomes diffused horizontally and perpendicularly throughout the cord, so that reflex phenomena, instead of being confined to a particular district, become more or less widely distributed; that the tone of muscles, and consequently the action of the sphincters, is due to reflex action in constant automatic operation; and, lastly, that the nutrition of muscles and probably of other tissues, and secretions, are largely influenced directly or indirectly by the spinal cord.

*h.* We deem it only necessary to remark in conclusion upon the olfactory and the optic nerves. There is reason to believe, partly on anatomical, but also on pathological, grounds, that each olfactory nerve,

unlike every other nerve, is connected chiefly with the supreme centre of its own side. The arrangement and course of the optic nerves are peculiar. But experiment and clinical observation demonstrate facts in relation to them which anatomy alone does not teach us. We have shown that destruction of the supreme centre of sight on one (say the left) side causes general amblyopia of the right eye, a result which equally follows destruction of the right optic nerve; whereas destruction of the optic tract, corpora geniculata, or

FIG. 95.—Scheme of decussation of optic tracts.

LE and RE, left and right eyes; C, chiasma; LG and RG, left and right geniculate bodies; Q, corpora quadrigemina; LH and RH, left and right centres of vision; *b* and *a*, nerve-fibres from left and right sides respectively of left eye; *b*, and *a*, corresponding fibres from right eye.

corpora quadrigemina or of the occipital lobe of one side causes hemianopia of both eyes. A reasonable explanation of all except the last of these phenomena is offered in the accompanying diagram, for which we are indebted to Prof. Charcot.

11. *Sympathetic system*.—The sympathetic system of nerves appears to have its supreme centre in the medulla oblongata, or rather on the floor of the fourth ventricle, but it is intimately interwoven with the spinal system, and, as is well known, each spinal nerve receives branches from, and transmits branches to, a neighbouring sympathetic ganglion. We need not consider the anatomical details of this system; it is sufficient to point out that it presides over the shortening and lengthening of the organic muscular fibres wheresoever situated, that it determines the dilatation and contraction of the blood-vessels,

and therefore the amount of blood supplied to various parts, and in some degree the rapidity of its flow through them, and that it thus regulates to some extent the nutritive and other functions of the different parts of the organism, and their temperature. There is reason also to believe that special branches are supplied to the secreting cells of glandular organs, and that hence a direct influence is exerted by it over the physiological processes which go on in these organs.

12. *Arteries of brain*.—The meningeal arteries are derived mainly from branches of the external carotids; but a minute branch is furnished also by each vertebral immediately after its entrance into the skull. They have no connection with the arteries which supply the brain and its vascular membrane, the pia mater.

The proper arteries of the brain are derived from the internal carotids and the vertebrals, which, after entering the skull and giving off certain branches, to some of which we shall presently again refer, form between them that remarkable anastomosis known as the circle of Willis. Each internal carotid artery, having first given off the ophthalmic and then the posterior communicating artery, divides into two branches,

namely, the anterior and the middle cerebral. The *anterior cerebral* (figs. 94, 96, 97, 98), which is the smaller of the two, anastomoses after a short course with its fellow by the anterior communicating artery. Its trunk then turns round the anterior edge of the corpus callosum, and runs backwards along the upper surface of that body. It divides into three principal branches, of which the first is distributed superficially to the orbital convolutions below, and to a small portion of the inner aspect of the hemisphere in the neighbourhood; the second is distributed to

the first frontal convolution, to the greater part of the second, to the upper extremity of the ascending frontal, and to all that part of the inner aspect of the hemisphere which lies between the area of distribution of the first branch and the ascending limb of the fronto-parietal fissure, including the anterior two-thirds of the corpus callosum; the third branch supplies that area of the inner surface of the hemisphere which lies between the ascending limb of the fronto-parietal and the parieto-occipital

fissure, and also the posterior part of the corpus callosum. The *middle cerebral* artery (figs. 94, 96, 97, 98) divides in the fissure of Sylvius into four branches, which, radiating in conformity with the convolutions of the island of Reil, and supplying them with vessels, emerge on to the outer surface of the brain, and are thus distributed:—the anterior or first branch ramifies over the third frontal convolution exclusively; the

FIG. 96.—Lateral view of brain, showing arterial areas.

FIG. 97.—Inner surface of cerebral hemisphere, showing arterial areas.

In the above figures, and also in Figs. 94 and 98, the dotted surfaces correspond to the anterior cerebral artery; the clear surfaces to the middle cerebral; the shaded surfaces to the posterior cerebral. The subdivisions of these surfaces made by dotted lines indicate the areas supplied by the principal branches of the above arteries, and the Arabic numbers attached to them the order of the branches from before backwards.

second is distributed to a portion of the second frontal convolution and to almost the whole of the ascending frontal; the third supplies mainly the ascending parietal and superior parietal convolutions, the posterior and lower limit of its distribution being indicated partly by the inter-parietal fissure, and partly by a horizontal line drawn from this to a point on the upper margin of the hemisphere midway between the fronto-parietal and parieto-occipital fissures; the fourth or posterior branch is distributed to the first and second temporal convolutions, and to the

FIG. 98.—Under surface of brain, showing principal convolutions and fissures and the arterial area.

gyrus angularis, its posterior limit being determined by a line drawn from the posterior extremity of the second temporal sulcus to the parieto-occipital. The *posterior cerebral arteries* (figs. 94, 96, 97, and 98) result from the division of the basilar; each sends branches into the brain-substance of the locus perforatus posticus, is then joined by the posterior communicating artery of the same side, and finally gives off three principal branches, which are distributed to all those parts of the cerebral surface which have been hitherto unaccounted for: the anterior to the uncinate convolution; the middle to the third temporal and the fusiform or lateral occipito-

temporal convolutions, and to the hinder part of the gyrus fornicatus; and the posterior to the median occipito-temporal convolution, to the cuneus, and to the occipital lobe.

The distribution of the arteries to the ganglia at the base of the brain is not less important than that upon the surface of the organ. All three pairs of cerebral arteries for the most part take a share in supplying these bodies. The anterior cerebral gives small branches to the anterior extremity only of the caudate nucleus, and not unfrequently none at all. The middle cerebral, on the other hand, has a comparatively wide and a very important distribution. It gives off many branches of somewhat large size, which, entering at the locus perforatus anticus at right angles, or nearly so, to the trunk, supply the whole of the lenticular nucleus of the corpus striatum, the whole or greater part of the caudate nucleus, the internal capsule, and the anterior and outer part of the optic thalamus. They may be divided into two groups: an internal group, consisting of

comparatively small vessels, which are distributed to the internal portions of the lenticular nucleus, and to the adjoining portions of the internal capsule; and an outer group of vessels of considerably larger size, which course mainly over the outer aspect of the lenticular nucleus, and supply the outer part of that body, and also, according to their position, the caudate nucleus or the optic thalamus. One of these branches, called by Charcot 'the artery of cerebral hemorrhage,' is pre-eminently large, and, after penetrating the outer part of the lenticular nucleus, and traversing the internal capsule, enters the substance of the caudate nucleus, and passes from behind forwards in it to its most anterior part. The posterior cerebral arteries give branches to the choroid plexuses and ventricular walls, and supply also the tegmentum, the corpora quadrigemina, and the posterior and inner parts of the optic thalami. The branches which they give to the last-named bodies may be divided into internal and external. The former supply the inner aspects of the thalami, and their rupture is apt to be followed by the profuse escape of blood into the ventricular cavities; the latter supply the outer parts of the thalami, and, since before they enter them they pass through the cerebral peduncles, their rupture is apt to be attended with effusion of blood into the substance of these bodies.

The vertebral arteries unite to form the basilar, which divides in front into the two posterior cerebrals. The vertebrals, besides supplying meningeal and spinal branches, give off on either side a posterior inferior cerebellar artery, which is distributed to the hinder portion of the lower aspect of the cerebellum and to the choroid plexuses of the fourth ventricle. The basilar, in addition to sending a branch to each internal ear and other branches to the substance of the pons, gives off also a right and a left anterior inferior cerebellar artery to the anterior part of the under surface of the cerebellum, and a right and a left superior cerebellar artery, which are distributed over the whole of the superior surface of the cerebellum, and supply the valve of Vieussens and partly the velum interpositum.

It is necessary to bear in mind (for, indeed, it is this fact which makes an accurate acquaintance with the details of the cerebral circulation important) that, save at the circle of Willis, little or no communication takes place between the branches of the cerebral arteries even down to their finest ramifications, excepting by means of capillary vessels; and that hence, if any artery become obstructed, the region to which it leads almost necessarily suffers in its whole extent. Thus, if the middle cerebral be blocked, the nutrition of the whole region to which it is distributed becomes impaired; if one of its primary branches be obstructed, the limitation of morbid change is equally definite; and if a secondary or even smaller vessel be alone involved, secondary changes will be limited to correspondingly minute districts. It is further important, in reference to this point, to know that the arteries on the surface of the convolutions give off long and short branches, which are quite distinct from one another; and of which the short are distributed to the cortical grey matter,

the long enter the white substance, and are limited in their distribution to it. The ultimate arteries supplying the ganglia are distinct from both.

It is a matter of no slight practical importance that the ophthalmic artery arises from the same trunk as that which gives off the anterior and middle cerebral arteries; and that it supplies not only the eyeball itself, but the contents of the orbit, including the lacrymal gland, and gives off branches to the eyelids and contiguous parts of the forehead and nose, and to the ethmoidal cells. The arteries of the internal ear again are mainly derived from one of the intracranial arteries, namely, the basilar.

13. *Veins of brain.*—The veins distributed over the surface of the cerebrum and cerebellum open into the several sinuses to which they are respectively contiguous. Those situated within the lateral ventricles converge to the venæ Galeni, by means of which they empty themselves into the straight sinus. It is needless to enumerate or trace the several sinuses. There are, however, two or three points in connection with the venous circulation of the brain which are important. These are:—first, that the cerebral and cerebellar veins all converge, directly or indirectly, to the lateral sinuses, and that hence all or nearly all the blood from these parts is returned by the internal jugular veins; second, that the ophthalmic vein, which has almost exactly the same distribution as the ophthalmic artery, empties itself into the cavernous sinus on the one hand, and on the other anastomoses with the branches of the facial and other veins; and, third, that the longitudinal sinus communicates with the veins on the exterior of the skull through the parietal foramen, and the lateral sinuses with those of the head and neck through the mastoid foramina.

### B. Pathology

Most diseases of the nervous system may affect any part of that system; and hence, although in many cases producing symptoms indicative of their specific nature, they tend also to evoke symptoms referrible to the particular regions of the nervous organism which they involve, and to the degree and manner in which they involve them. As regards the last point it is obvious that here, as elsewhere, the functions of parts may be impaired, exalted, or perverted. And, as regards locality, it is clear that disease may involve some portion of the motor tract, some portion of the co-ordinating tract, or some portion of the sensory tract; that it may be seated either in the peripheral nerves, in the cord, or in the intracranial centres; and that the symptoms will vary accordingly. Further, if the supreme centres be involved, there will be not only pathological sensory or motor phenomena, but also phenomena referrible to the intellectual and emotional functions. We proceed to discuss some of the more important phenomena which are dependent on the situation of the parts affected, and on the degree and manner of their involvement.

#### 1. Motor Paralysis. Paresis

By paralysis is meant the impairment or loss of that power which the different motor centres should exert over the movements of the muscles.

The term 'paresis' is often used of the slighter forms of this condition. Paralysis of the voluntary muscles, to which alone we now confine our attention, may vary from the slightest degree of impairment of voluntary power over them to that condition in which every trace of such power has disappeared, and the part affected is absolutely motionless and incapable of motion. The quality, also, of this paralysis varies in different cases. In some, as in general paralysis of the insane and disseminated sclerosis, the enfeebled muscles become tremulous under the attempt to use them ; more commonly, as in most cases of ordinary hemiplegia, their movements are slow, weak, and halting, but uniform. In some instances the paralysed muscles retain their normal bulk, in some they waste. Sometimes they are flaccid, sometimes they preserve their natural tonicity, sometimes they are rigid and perhaps contracted. In some cases, again, they more or less completely lose the power of reacting to faradism or other forms of irritation ; while occasionally their contractility remains unimpaired or even increases. And, lastly, in different cases the electro-sensibility of the affected muscles becomes weakened or exalted, or remains unaffected.

*a. Cerebral paralysis.*—i. *General paralysis* seldom occurs excepting in association with insanity, and is then due, as might be supposed, to some general impairment of the surface of the brain. It is for the most part slight in degree, and indicated by feebleness, not only of the muscles of the limbs, but of those of the trunk, head, and neck, and of those of expression, mastication, and deglutition. Further, as has already been pointed out, the muscles are usually slightly tremulous when put into action.

ii. *Hemiplegia*, or paralysis limited to the distribution of the motor nerves of one side of the body, is due as a rule to disease of the opposite cerebral hemisphere, corpus striatum, or crus. Its most common cause probably is disease implicating the corpus striatum or the white matter immediately external to it ; and it is in such cases that hemiplegia presents its typical characters. The paralysis, as has been observed, is limited to the opposite side of the body ; but it does not affect the whole side uniformly ; for while some nerves are almost always affected in a greater or less degree, others almost invariably escape or suffer very slightly. Those which escape are such as act in association with corresponding nerves of the opposite side, whose combined actions we cannot voluntarily restrain, and whose nuclei are probably (as Dr. Broadbent suggests) more intimately connected with one another than are the nuclei of other symmetrically placed nerves, and are hence influenced in a greater degree than these by motor impulses which descend from the other side of the brain. The third, fourth, and sixth nerves seldom if ever suffer, so that the motions of the eyeball on the affected side continue, for the most part, perfect. Again, the motor root of the fifth nerve suffers, as a rule, but little. The portio dura, on the other hand, generally is distinctly though slightly and unequally involved ; hence on the affected side the face is usually more or less blank, the muscular wrinkles being partially effaced, the eye a little more open than its fellow, and winking somewhat laggingly performed,

and the mouth is drawn to the opposite side; nevertheless the eye can generally be perfectly closed, and some power of movement remains in the whole of the side of the face, but more especially in its upper half. The hypoglossal is almost invariably markedly involved, and the tongue consequently is protruded with its tip pointing towards the paralysed side, while, on being drawn in again and often when it lies quiescent on the floor of the mouth, its median furrow is concave towards the unparalysed side, and its tip looks in the same direction. The motor fibres of the par vagum, and the motor roots of the spinal nerves going to the muscles of the head and neck and trunk, suffer but little; and hence the patient as a rule has no difficulty in deglutition, in phonation, in maintaining the due position of his head, in respiration, or in acts needing the employment of the muscles of the abdomen or back. The nerves of the arm and leg are always chiefly affected. If the case be severe both limbs are alike motionless; but it is a curious fact that if there be a difference between them it is generally that the leg retains a greater degree of motor power than the arm, that it is the last to fail, the first to recover, and that the distal parts of the limbs are generally more completely paralysed than the proximal parts. But the distribution of paralysis is liable to variation, and occasionally the leg escapes wholly, occasionally it is affected in a higher degree than the arm, and sometimes the hand or foot suffers less than the arm or leg.

Disease situated in the substance of the hemisphere is also generally attended with hemiplegia; especially disease occupying the frontal or parietal lobe. And it is in such cases that our diagnosis of the seat of mischief and the cause of mischief may be aided by the facts which have already been discussed, with regard to the localisation of function in the grey matter of the convolutions, and the area of distribution of the cerebral arteries. If the hemiplegia be attended with aphasia we may assume that either the posterior part of the third frontal convolution, or else the wedge of white matter extending thence to the corpus striatum, is involved.

When the lesion is situated in the crus cerebri, together with hemiplegia of the opposite side of the body, there will probably be paralysis of the third nerve of the same *side*. AER

*b. Bulbar paralysis.*—When paralysis arises from disease of the medulla oblongata or pons Varolii, it is obvious, from the abundance and close proximity of important nerves and nerve-nuclei in these organs, and from the fact that the sensory and motor strands from both cerebral hemispheres here meet and blend, that such one-sided limitation of paralysis as occurs in hemiplegia is scarcely likely to be present, and that if there be general paralysis it must differ largely in its details and in its danger to life from that which has before been adverted to. It is mainly in such cases that what is called *cross paralysis* is met with—paralysis, that is to say, of one side of the body and of the opposite side of the face. It is in such cases, again, that we sometimes find paralysis of both arms and legs, or of one arm and both legs, or the converse. And, moreover, it frequently happens,

for obvious reasons, that there is paralysis of the muscles of one or other or both eyeballs, or of one or other or both facial nerves; or that there is difficulty of articulation, phonation, mastication, deglutition, or respiration, or of control over the rectum and bladder; or that a greater or less number of these paralyse occur in combination. It must be recollected, in reference to these cases, and equally in reference to diseases involving the under surface of the brain, that, together with the opposite or hemiplegic paralysis due to involvement of nerve-tissue above the nerve-nuclei, we are always apt to have paralysis, generally of the same side, due to the direct implication of nerve nuclei, or of nerves after their emergence from their nuclei. It is by this circumstance that cross paralysis is to be explained. The great danger to life which, as is well known, attends disease of the parts now under consideration is due mainly to paralysis of the nerves supplied to the organs of deglutition, respiration, or circulation, which is almost always present in a greater or less degree.

*c. Spinal paralysis. Paraplegia.*—When paralysis is due to disease of the spinal cord, it generally goes by the name of paraplegia, and is specially characterised by the fact that the paralysis involves only the muscles supplied by those nerves which are given off from the cord at and below the seat of disease. The symptoms will of course vary, both with the situation and with the extent of the lesion. Thus if it involve the whole thickness of the cord high up in the neck above the origin of the phrenic nerves, there will be complete motor paralysis of all parts seated below—of the arms and legs, as also of the diaphragm and other respiratory muscles. If it be situated at or above the origin of the brachial plexus, the movements of the diaphragm will be unaffected, but the arms and legs will be paralysed as in the former case. If the dorsal region of the spine suffer, the arms will necessarily escape, and the paralysis will be limited to the lower extremities and to just so much of the lower part of the trunk as is supplied by nerves given off below the seat of mischief. In all such cases there is interference with the functions of micturition and defæcation. For the most part if the disease be situated above the lumbar centres for causing contraction of the bladder and rectum, and those which regulate the sphincters, the bladder and rectum contract upon their contents when they become distended by them, the sphincters yield, and the evacuations are discharged involuntarily. If the disease be low down and involve the lumbar centres themselves, the urine escapes continuously and there is a tendency to the same thing as respects the feces. The bowels are usually constipated in paraplegia. It need scarcely be added that in complete paralysis sensation as well as motion is annulled.

But paralysis below the seat of lesion is not necessarily complete. In many cases where it is due to pressure, or to disease of the surface of the cord, or of the structures which surround it, sensation remains perfect, or nearly so, while motorial power is wholly lost. In many cases, again, the paralysis, though involving all parts below equally, involves them only to the extent of impairing their power of motion. Further, many cases are met with in which the disease implicates unsymmetrically certain defined

tracts only of the cord. The consequences are often very remarkable. If one lateral half be diseased in its whole horizontal extent, but to a limited extent vertically, complete paralysis necessarily involves all the motor nerves given off from the cord on the same side as the lesion, but below it, in consequence of the lesion having cut off all direct connection between them and the brain above. But, inasmuch as the decussation of the sensory nerves takes place in the cord itself immediately after their entry into the cord, it follows that the sensory nerves associated with the paralysed region remain unaffected, while those of the corresponding region of the opposite side of the body share the fate of the motor nerves of the diseased side. Hence arise: paralysis, with retention of normal sensation on the one side; anæsthesia, with perfect power of motion, on the other side; and in some cases a more or less distinct line of anæsthesia forming, on the side of the lesion, the upper limit of the region of motor paralysis. Perfect unilateral limitation of disease is of course rare; it is more usual to find one side involved in a portion only of its horizontal extent, or both sides involved more or less, and in unequal degrees; under which circumstances the resulting paralytic phenomena are of course less typical, and irregularly distributed.

It is a curious fact, which will hereafter be more fully considered, that certain forms of disease have a remarkable tendency to involve particular regions or strands of the cord, and to be limited to them. The parts to which particular reference is here made are the posterior columns, the lateral columns, and the groups of large or motor cells in the anterior cornua. When disease affects the posterior columns only, or, as Charcot points out, the outer bands of these columns which abut directly on the inner aspects of the posterior cornua and roots of the sensory nerves, the condition known as locomotor ataxy, or, in other words, loss of co-ordinating power, and not ordinary motor paralysis, involves the voluntary muscles of all those parts which are below the seat of disease. In a large proportion of cases the legs alone suffer, but the arms and even parts above the arms are all liable to become implicated. Inco-ordination is shown: partly by loss of the muscular sense, in virtue of which the patient is unable to judge of the amount of force needed to accomplish definite results, and unable therefore (especially if his eyes be closed) to determine the position of his affected limbs in relation to other parts of his person or to surrounding objects; and partly by want of control over his voluntary movements, which are consequently more or less violent than necessary, and involve a larger or smaller number of muscles than are suitable for their execution. There is not, however, any necessary loss of muscular strength, and the affected limbs sometimes retain extraordinary power. When the lateral columns only are the seat of disease, or more particularly the white matter which lies behind the horizontal line drawn laterally through the median canal, motor paralysis ensues in all those parts which are situated below the seat of lesion; but under these circumstances the muscles of the affected limbs tend to get, not only paralysed, but at first tremulous, and ultimately rigid and

contracted. If the groups of large cells in the anterior cornua are diseased, then only the nerves which take their origin in them, and the muscles which these nerves supply, suffer: the muscles become paralysed, and in a large number of cases speedily lose their faradic contractility, and waste.

*d. Nerve paralysis.*—In the foregoing account we have considered more especially those forms of paralysis which are due to disease occurring above the nuclei of origin of the paralysed nerves. We have, however, referred here and there to the fact that paralysis may be caused by disease involving either these nuclei, or the nerves after their emergence from them. We have, indeed, in considering paralysis due to disease originating within the brain or cord, been almost compelled to advert to the fact that, when certain parts, more especially the pons, medulla oblongata, base of the brain, or spinal cord, are affected, the paralysis which ensues is necessarily apt to be compounded of paralysis due to the cutting off of the connection between nerve-nuclei and the higher centres, and of that dependent on direct implication of nerve-nuclei or nerves. Paralysis from destruction of a nerve or of its nucleus of origin, is necessarily of very limited distribution; it affects a single muscle or a group of muscles, as, for example, the external rectus of one eye, or the superior oblique, or the other muscles of the eyeball together with the levator palpebræ, or the muscles of expression of one side of the face, or certain muscles of the head and neck, trunk, or extremities. It also tends soon to become absolute. It is not, of course, denied that other varieties of paralysis are often absolute; but, as we have pointed out, in ordinary well-marked hemiplegia certain nerves appear to escape implication, and certain others, such as the portio dura, become involved only to a slight extent. In primary paralysis, however, of the portio dura, the paralysis of the muscles which it supplies is for the most part general and complete. Further, the paralysed muscles usually rapidly lose the power of responding to the faradic stimulus, and at the same time grow flaccid, and waste.

*e. Disease of the cerebellum.*—Diseases of this part are, no doubt, often attended with loss of sight, and with hemiplegia; but these phenomena are accidental accompaniments of cerebellar lesions, and due either to the direct implication of some neighbouring part, to pressure exerted by the diseased cerebellum on the adjoining quadrigeminal bodies or subjacent medulla oblongata, or to optic neuritis. The usual and natural result of cerebellar disease is a staggering gait like that of a drunken man, or in extreme cases a total inability to stand or walk: in consequence, not of muscular debility, or of mere inco-ordination of the movements of the lower extremities, as in tabes dorsalis, but of a general impairment or loss of the power of maintaining equilibrium. Nystagmus and parallel deviation of the optic axes are liable to occur in affections of the cerebellum; as also the tremulous movements of the head and neck and arms, like those of disseminated sclerosis, when their muscles are put into action.

*f. Condition of muscles in motor paralysis. i. Tone.*—In some cases of

paralysis the muscles retain their normal tonicity ; in some they get limp and flaccid ; in some they become rigid and contracted. The normal tonicity is preserved in a large number of cases of both cerebral and spinal paralysis. It is essential, indeed, for its conservation that the connection between the muscles and the cord remain intact. Limpness of muscles not unfrequently attends those cases of paralysis of the same centres in which the affection which causes paralysis is sudden in its onset and extensive ; it generally also soon becomes developed in those muscles whose nerve-nuclei are directly implicated, and in those whose connection with these nuclei is interrupted. Rigidity or contraction of the muscles in cerebral or spinal disease is often the consequence of some irritation, inflammatory or other, going on at the seat of disease. It is then to be regarded as an acute condition, and generally comes on early. But rigidity, with contraction, mainly of the flexor muscles, is apt to ensue gradually in cases of old paralysis : sometimes, in the case of atrophied muscles, from their gradual and slow longitudinal contraction ; more frequently perhaps, in consequence of secondary degenerative changes going on in the lateral columns of the cord.

ii. *Electric contractility and irritability* will be specially discussed later on, under the head of 'Electricity in nervous diseases.'

iii. *Nutrition*.—In a considerable number of cases paralysed muscles retain their bulk and texture, or at most become slightly impaired in these respects, as even non-paralysed muscles are apt to do, from mere disuse, and hence remain in a condition to take on active duty so soon as the cause of paralysis disappears. This is generally the case when the cause of paralysis lies above the nuclei of origin of the paralysed nerves. In these cases, also, the muscles generally retain their tone and faradic contractility little or not at all impaired. When, however, the motor nuclei, or nerves emanating from them, are the seat of disease, rapid muscular emaciation usually takes place concurrently with loss of faradic contractility. To this subject we shall subsequently recur.

iv. *Reflex action*.—The involuntary movement of paralysed muscles in obedience to irritation of sensory surfaces is a phenomenon of common occurrence. Reflex muscular action occurs of course constantly in health, and when met with in cases in which voluntary power over muscles is impaired or lost necessarily implies that the afferent nerves which convey impressions from the seat of irritation to the cord, the motor nerves passing from the cord to the muscles which are called into action, and the part of the cord with which these several nerves are connected, retain in a greater or less degree their normal powers. Reflex excitability, therefore, may be impaired or annulled by disease or injury of any part of this nervous mechanism, and it may be increased in consequence either of the simple removal of the restraining power exerted by the higher centres over that of the cord, or by morbid irritability of the dynamical elements of the cord.

Two varieties of reflex action are recognised : one dependent on impressions conveyed by the ordinary afferent or sensory nerves, mainly those of the skin ; the other evoked in a stretched or tense muscle by any sudden

traction made upon it, either through a sharp blow inflicted on its tendon, or by some other manœuvre.

The former variety, or the superficial reflex, for the most part undergoes diminution on the paralysed side in cases of hemiplegia. On the other hand, it becomes markedly augmented in the paralysed regions in paraplegia due to disease simply interrupting the continuity between the upper and lower parts of the cord. In such cases, sometimes under the influence of defæcation or micturition, sometimes from the irritation of bed-clothes, but more strikingly from touching or tickling the soles, the paralysed limbs perform movements which were formerly regarded as voluntary. When one sole is irritated the corresponding limb may be made by successive efforts to become powerfully flexed at the hip, knee, and ankle joints, while the toes are widely separated and extended. In most cases the reflex movements are limited to the irritated member; but in some instances both limbs become involved, and occasionally the muscular contractions are still more widely distributed.

The presence of this reflex phenomenon implies that the nerves of the sacral plexus and the corresponding part of the cord are still capable of performing their special functions. Other reflex phenomena tending to throw light on the condition of different regions of the spinal cord, and of the sensory and motor nerves connected with them, have received, and on diagnostic grounds deserve, attention. Thus: irritation of the skin of the buttock causes reflex contraction of the glutei muscles through the agency of the fourth and fifth lumbar nerves; irritation of the inner aspect of the thigh causes retraction of the testicle through the agency of the first and second lumbar nerves; irritation of the skin of the abdomen from the ribs downwards causes, by means of the dorsal nerves (eighth to twelfth inclusive), contraction of the abdominal muscles; irritation of the skin of the thorax between the fifth and seventh ribs leads to muscular contraction in the epigastrium, due to the agency of the fourth and the lower three dorsal nerves; irritation of the skin in the interscapular region excites, by means of the last two or three cervical and first two or three dorsal nerves, contraction of some of the scapular muscles; and irritation of the palm through the instrumentality of the same nerves causes reflex phenomena in the arm. It may be added to the list that irritation of the conjunctiva causes reflex closure of the eye; and that in cases of hemiplegic paralysis a paralysed limb or group of muscles occasionally executes sudden movements under the influence of emotional excitement.

The so-called 'reflex' phenomena, which are developed when sudden tension is applied to muscles, are of much clinical interest and importance. By Erb, who first drew special attention to them, they were regarded as strictly reflex phenomena; but by Westphal, who also early investigated the subject, they were considered to be due to the immediate contraction by their own inherent power of the suddenly stretched muscles. Many arguments are adducible, and have been brought forward, in favour of the former view; but that the latter is the true one seems to be established by the fact that the tendon reflex phenomena are evoked in

much less time than true reflex phenomena are, and indeed in less time than (according to our present knowledge) it is possible for nerve influence to be conveyed from the sensory starting-point to the cord, and thence back to the muscles which contract. The interval which elapses between the primary irritation and the muscular response in the case of the tendon reflex appears to be about one-third of that observed in true reflex action. It is to Dr. Augustus Waller that the experimental determination of this important point is due; and his conclusions have been confirmed by the later inquiries of Dr. Gowers, Dr. de Watteville, and others. At the same time there is ample proof that there is an intimate relation between the tendon reflexes and true reflex action; for tendon reflexes cannot be obtained when the conditions necessary for the development of ordinary reflex phenomena are absent, and their development is evidently dependent on the presence of muscular tone, which itself is due to the fact that the afferent and efferent nerves concerned and the intervening nervous matter of the cord discharge their normal functions. The tendon reflexes can only be evoked from muscles which are the subject of passive tension.

The phenomena here referred to are doubtless of general distribution. But there are two or three which have been particularly studied, and are of special clinical importance.

The first of these is the *patellar tendon reflex*, the pathological relations of which were first investigated by Erb and Westphal. This is the sudden contraction of the quadriceps extensor femoris and jerking forwards of the foot, which may generally be caused in health by striking sharply the patellar tendon when the leg is allowed to hang pendulous either over the edge of a bed or chair or by crossing the one limb over its fellow, so as to put the extensor muscles slightly on the stretch. In order to elicit the phenomenon the limb should be allowed to hang loosely, and the patient should be taken unawares; for it may often be counteracted by voluntary effort or expectant rigidity of muscles. In cases in which the reflex is feeble it is necessary to strike the patellar tendon sharply with some heavy instrument, such as a percussion hammer; but in cases in which it is aggravated or even well-marked a mere filip with the finger-nail is often sufficient to excite it; and it may often then be developed by striking the patella itself.

Another phenomenon of the same kind may be produced in the foot when, after having slightly extended the muscles of the calf, the Achilles tendon is struck; another in the forearm when, under similar circumstances, a sharp blow is inflicted on the tendinous attachment of the extensor muscles of the upper arm to the olecranon process; another in the hand by striking the tendons at the wrist, and another (Dr. de Watteville's *jaw-jerk*) in the lower-jaw, if a spatula be placed between the teeth and struck sharply from above, so as to cause sudden downward movement of the jaw.

A further phenomenon of the same class is that known as the *ankle-clonus*. If in certain cases (mostly paralytic) the patient's foot be grasped in the hand and then suddenly flexed so as to put the muscles of the calf

on the stretch, a sudden contraction of these muscles takes place, attended with a corresponding extension of the foot. So far the result seems identical with those which have been above described; but if in such cases the pressure be continued, a series of alternate contractions and relaxations generally occurs, which are rhythmical and, according to Dr. Gowers, at the rate of from six to ten in the second, and persist as long as the pressure is maintained or until the muscles become tired. In order to elicit the clonus it is desirable that the leg be not fully extended on the thigh; and in some cases its development is promoted by sharply tapping the Achilles tendon. Occasionally the tremors extend from the muscles of the leg to those of the thigh, and even to the opposite extremity. And further, in cases in which the clonus is present, similar tremulous movements are excited when, in attempting to walk, the patient throws his weight on his toes. It is apparently also of the same nature as the phenomenon which, when arising under other circumstances, is sometimes termed spinal epilepsy. Occasionally, owing to the action of the peronei, the oscillations of the foot are lateral. Other cloni may be obtained: one at the patella by suddenly and forcibly pushing this bone downwards towards the leg, and maintaining this pressure; one in the hand by grasping the tips of the fingers and forcibly pressing the hand backwards; one in the great toe by means of a similar movement; and one in the jaw.

If, in certain cases, the extensor muscles of the leg be put on the stretch by passive flexion of the foot, and then the muscles of the front of the leg be tapped, the calf muscles contract and momentarily extend the foot exactly as they do when the tendo Achillis is stretched. This is Dr. Gowers's 'front tap contraction,' and is a very delicate test of increased irritability.

The so-called tendon reflexes, like the superficial reflexes, are for the most part observable in healthy persons; and like the latter are liable to become increased, or to suffer diminution, or even to disappear in disease. They disappear, as true reflex action does, whenever there is interruption in the course of the sensory or motor nerves of the parts concerned, or in the communication which exists between them in the spinal cord; they disappear, moreover, for the most part in tabes dorsalis, in infantile paralysis, in pseudo-hypertrophic paralysis, in the course of diphtheritic paralysis, and in peripheral neuritis. They diminish also or disappear during the later stage of diabetes mellitus. They become heightened mainly in affections of the lateral columns of the cord, and hence in lateral sclerosis, as a general rule in disseminated sclerosis and paraplegia from pressure, and in the early stages of diphtheritic paralysis. Ankle clonus is rarely if ever observed in health, and is often taken to indicate the presence of actual disease of the spinal cord, and is hence a phenomenon of some diagnostic importance. But it may occur in cases of hysterical paraplegia; Drs. Hughlings Jackson and Beever have noticed it temporarily after attacks of epilepsy; it is commonly present in persons under the influence of anæsthetics; and it is often observed in patients suffering

or convalescent from exhausting diseases. The other cloni are also seldom met with apart from the presence of central nervous disease.

The superficial and tendon reflexes, though often exaggerated or defective in the same case, may be modified in character quite independently of one another. Thus the patellar reflex and ankle clonus are almost without exception absent in tabes dorsalis, while as a general rule ordinary reflex phenomena persist; and in hemiplegia, in which for the most part the superficial reflexes diminish on the affected side, tendon reflexes usually become excessive.

v. *Irritability*.—When stimuli are applied directly to muscle it contracts in virtue of its inherent irritability. This quality, which belongs to healthy muscle, is often diminished or aggravated in disease. It is a fact of much practical importance that irritability is for the most part increased in the earlier stage of those affections, due to disease of the anterior grey horns or of motor nerves, in which muscles are rapidly wasting, tendon reflexes have diminished or disappeared, and the electrical reactions of degeneration (to be described hereafter) are present. In such cases a sharp tap, made for example by the percussion hammer or ear-piece of the stethoscope, on the belly of any of the affected muscles readily causes contractions of the muscle with movement of the part into which it is inserted. This phenomenon, the significance of which is quite distinct from that of the tendon reflex, if not opposed to it, is nevertheless often confounded with it. It is generally associated with more or less considerable tenderness of the affected muscular tissue. The condition of muscles here referred to is exemplified in lead palsy, acute or subacute anterior poliomyelitis, and paralysis due to affection of peripheral nerves.

## 2. *Anæsthesia. Analgesia*

Anæsthesia, or impairment or loss of sensation, may, like motor paralysis exist in various degrees, and occupy various regions of the body. It may be limited to the skin or muscles, or may involve the whole thickness of the part affected. The last variety is the most common. In its slighter degrees it is often attended with tingling, pricking, formication, or sense of numbness; and the affected part, in relation to things with which it is brought into contact, feels to the sufferer as if protected or covered by some thick soft texture. If his hands be the seat of anæsthesia, they seem as if clothed with thick gloves; if his feet, as if he were walking on cotton-wool or other soft yielding material. In extreme cases the skin and subjacent parts are wholly insensible to external impressions, and admit of being pricked, cut, burnt or otherwise injured, without the knowledge of the patient. In most cases abeyance of ordinary tactile sensibility is attended with similar abeyance of the capacity for distinguishing painful impressions, and heat and cold; but this is not always so, for now and then the capability of recognising these latter impressions appears to survive in some degree when the capability of distinguishing the former is wholly lost, and, on the other hand, tactile sensibility occasionally remains

perfect, or but little impaired, in cases presenting absolute insensibility to pain (*analgesia*)—facts which have led some physiologists to believe that these different forms of sensation travel to the sensorium by different routes. Muscular sensibility is sometimes impaired or lost in cases of paralysis while the cutaneous sensibility remains unaffected; and occasionally in hysterical cases muscular insensibility, with or without cutaneous anæsthesia, goes along with unimpaired muscular contractility.

There are a few other points connected with anæsthesia which claim attention. The first of these is the fact that persons suffering from anæsthesia often experience subjective sensations referrible to the anæsthetic regions, and not unfrequently complain of neuralgic and other pains in them. The second is that sometimes, when sensation is greatly impaired, the patient does not take cognisance of impressions made on the affected part until after the lapse of a few seconds, or it may be as much as half a minute—the impression being delayed in its transmission to the sensorium. The impressions thus delayed are generally those of pain and temperature. The third is the fact that under similar conditions there is often a peculiar difficulty in distinguishing between the characters of different impressions. The last to which we shall refer is the circumstance that, inasmuch as it is through the sensory or afferent nerves that reflex motor phenomena are excited, it is obvious that if the disease causing anæsthesia exist in the course of the nerve or in its nucleus, no irritation of its extremity can evoke reflex action, while, if it be due to spinal disease, the probability is that irritation of the extremities of the anæsthetic nerves given off below the seat of the disease will excite muscular action in the corresponding muscles. Similar phenomena to the last, but of a more complicated character and higher order, are not unfrequently produced through the agency of the nerves of sight and hearing.

*a. Cerebral anæsthesia.*—i. *General impairment of sensibility* may attend the general paralytic condition which is associated with a special form of insanity. It occurs also in hysteria.

ii. *Hemianæsthesia* may arise, like hemiplegia, from disease of one of the cerebral hemispheres or of the ganglia or crura immediately connected with it. It is, however, of much less common occurrence than hemiparalysis, and rarely occurs independently of it. Experiments on the lower animals and pathological observation concur to prove: that the optic thalamus has the same kind of relation to sensation that the corpus striatum has to motion; and that lesion of this part is attended with anæsthesia of the opposite side of the body. As a matter of fact, however, hemianæsthesia is generally due to lesion, not of the optic thalamus, but of the internal capsule in relation with the optic thalamus, or of that portion of the commencement of the corona radiata which contains the fibres of communication between the optic thalamus and corresponding cerebral hemisphere. Cerebral hemianæsthesia, unlike cerebral motor paralysis, is for the most part universal throughout the affected side; and in connection with it there may be anæsthesia of certain of the nerves of special sense—deafness of the corresponding ear, loss of smell in the

corresponding nostril, loss of taste on the corresponding side of the tongue, and impairment or loss of sight in the corresponding eye, in some cases only colour-blindness. As regards loss of sight in the eye opposite the cerebral lesion it may be observed that this seems to occur when the lesion implicates the internal capsule. A case of Dr. Jackson's would seem to show that disease of the optic thalamus itself tends rather to cause hemianopia of both eyes.

Theory, and to some extent experience, would lead us to believe that disease affecting the temporo-sphenoidal and occipital lobes, and the posterior part of the parietal lobe, would be more likely to be attended with anæsthesia, than with motor paralysis, of the opposite side of the body. And in connection with this subject it is important to recollect the position of Ferrier's centres of vision, hearing, smell, taste, and touch.

Affections involving the tegmentum of the crus would of course be attended with more or less marked hemianæsthesia of the opposite side.

Hemianæsthesia is in some cases absolute, the patient feels nothing; but more frequently it is incomplete—he feels generally in some degree; or he retains more or less sensation in certain parts, especially the palm or sole, or certain areas of the leg or forearm; or, as occasionally happens, the affected side is irregularly studded with anæsthetic patches. Not unfrequently patients who are incompletely hemianæsthetic experience considerable pain when their paralysed limbs are moved, and refer the sensation due to pricking and other forms of pain inflicted on them to a joint or some other part remote from the seat of injury; and at the same time wholly misconceive the character of the impression.

*b. Bulbar anæsthesia.*—When disease involves the pons or medulla oblongata, some degree of anæsthesia is very apt to be associated with motor paralysis, and, like it, to be of irregular distribution. Of course all the sensory nerves which take their origin in these parts are, like the motor nerves, liable to be implicated.

*c. Spinal anæsthesia.*—Anæsthesia from spinal disease, like that from cerebral disease, is far less common than the corresponding paralytic affection, and is rarely met with apart from it. There are several reasons for this: the sensory tracts of the cord are limited almost exclusively to the posterior cornua, and the rest of the grey matter behind the central canal, so that they are apt to escape pressure and the other consequences of disease occupying the periphery of the cord or the surrounding tissues; moreover, it seems to be proved by experiment that a narrow thread of grey matter is sufficient to maintain an effective connection between the sensory tract below and that above. Disease limited to the central region of the cord, or rather to the posterior part of this region, might conceivably induce anæsthesia without paralysis. We have previously pointed out the important fact that disease of one lateral half of the spinal cord, interrupting the longitudinal continuity of the fibres, causes anæsthesia of the opposite side of the body.

*d. Nerve anæsthesia.*—Local anæsthesia, like local paralysis, may arise from disease affecting either a sensory nerve or its nucleus, and thus necessarily occupies the same side of the body as that on which the lesion exists. Such anæsthesiæ are not unfrequent in the area of distribution of the fifth pair or some of its branches, or in that of one or other of the spinal nerves. The anæsthesia which forms the upper boundary of the paralysed region in cases of unilateral injury or disease of the cord is a typical example of this condition. The nerves of special sense may suffer equally with those of common sensation.

### 3. *Convulsions. Spasms*

In speaking of paralysis, we have referred to the facts, that associated with this state it is not uncommon to observe tremulousness of muscles, arising especially during voluntary efforts, and that paralysed muscles occasionally become rigid and contracted. It may be added that convulsive movements of various kinds are not unfrequently associated with paralysis. They more frequently occur, however, independently of it.

Convulsions may affect single muscles or portions of muscles, groups of muscles, a limb, the head and neck, one half of the body, or the whole of it. They may be intermittent or continuous, and may vary in intensity from a scarcely perceptible flickering of the muscular fibres to contractions of such violence and strength that the muscles become ruptured. Intermittent contractions are termed *clonic*, persistent contractions *tonic*.

The slighter forms of convulsions are exemplified in the tremulous, more or less rhythmical, movements which are observed under many various conditions, and generally cease during sleep. Some of these attend efforts at voluntary movement only, and are then usually regarded rather as evidence of debility than as convulsions in the true sense of the term, on the ground that they depend on the intermittent transmission of voluntary impulses only. In true convulsions there is a similar intermittent transmission, but the force is exerted independently of and beyond the will. This distinction is useful to bear in mind, but is not always available in practice, if indeed the two conditions do not frequently run into one another. Among the convulsions which, on the above view, might be referred to debility are the fibrillar tremblings of the lips and tongue of patients suffering from general paralysis during their attempts to speak, and the irregularly rhythmical movements of the limbs which not unfrequently attend the voluntary efforts of persons labouring under disseminated sclerosis of the nerve-centres; among those which are truly convulsive may be enumerated that flickering of the orbicularis palpebrarum which is known by personal experience to all, the general tremulousness which attends exposure to cold and febrile rigors, the subsultus tendinum of patients in the typhoid condition, the rhythmical tremors of paralysis agitans and chronic mercurial poisoning, and the tremors which occasionally attack the lower extremities of paraplegic patients.

Another form of convulsion is that to which the term choreic may be applied, and of which chorea furnishes the most typical example. In this,

as in the former series, the movements cease during sleep, and, as in the paralytic form of trembling, are greatly aggravated during voluntary efforts and under mental excitement. Choreic movements are characterised mainly by their abruptness and irregularity, and by the fact that when they are engrafted on any voluntary movement they interrupt its progress by a series of grotesque contortions and diversions which are not then necessarily limited to the limb or organ which is making the effort. Choreic movements are not unfrequently hemiplegic, or even limited to a limb. Related in some degree to chorea are the grimaces, and other tricks of movement, to which some persons acquire an uncontrollable impulse; the peculiar rotatory and other rhythmical or irregular motions to which hysterical females are occasionally addicted; and especially perhaps the redundant and awkward movements of locomotor ataxy. A peculiar form of convulsion, also related to chorea, has been described by Dr. Hammond under the name of 'athetosis.' It is characterised mainly by continued slow movements of the fingers and toes, and inability to maintain them in any position. It generally ceases during sleep, and supervenes on hemiplegia in which more or less complete recovery of motor power has taken place.

The clonic convulsions of epilepsy and epileptiform conditions are characterised by more or less violent and rapidly repeated alternating movements—rapidly repeated alternate flexions and extensions of the arms or legs, jerkings of the head and neck, or similar movements of the muscles of the face or eyes. These, like choreic convulsions, are not unfrequently unilateral, but they may be general, or limited to a single limb or to part of a limb.

In tonic spasm or convulsion, muscular contractions take place, which are more or less enduring. It can readily be understood that the terms clonic and tonic can be employed only in a relative sense, and that clonic and tonic spasms pass into one another by insensible gradations. Tonic spasms are exemplified in the cramps which occur after fatigue in the muscles of the calf, or in various muscles in Asiatic cholera; in the contractions of the limbs or 'contractures' which take place in the course of some forms of paralysis; in the folding of the thumb into the palm, the gradual drawing up of the arm, or other comparatively slow and strong contractions of muscles, which are usually the earliest of the convulsive phenomena of the epileptic fit; and in the violent attacks of muscular rigidity which by their repetition constitute the characteristic sign of tetanus and strychnia-poisoning.

It is not always easy to localise the seat of the diseases causing convulsions. In reference, however, to this point, it must be recollected that all those parts which by their destruction cause paralysis of certain regions are necessarily likely under irritation to cause motor phenomena in the same regions. Thus, since hemiplegia is determined only by destructive disease of the opposite cerebral hemisphere, corpus striatum or crus cerebri, it might be taken for granted that convulsions affecting generally one side of the body must be caused by disease of the same parts.

It is probable on such grounds (but not on them alone) that choreic and epileptic convulsions, which are frequently unilateral, are of cerebral origin. It is important, however, to note that tremors of the muscles attending voluntary movements, such, for example, as occur in disseminated sclerosis, are often due to disease of the optic thalami, tubercula quadrigemina, cerebellum, or floor of the fourth ventricle. Again, since paraplegia depends upon disease affecting the cord, there is reason to suspect that convulsive affections presenting a similar arrangement are of spinal origin. Tetanus and strychnia-poisoning are cases in point, although it must be admitted that in both cases the lesion involves the medulla oblongata even more importantly than the cord. When a single muscle or group of muscles is affected, we must look to the origin of the nerve or nerves which supply it; and it is clear that theoretically the lesion might be referred, either to the nucleus of the nerve, or to a limited spot in the corpus striatum or in the grey matter of the cerebral convolutions in direct linear continuity with the nerve-nucleus. It may be observed, however, that the simpler and more restricted in area such limited convulsion is, the more likely is it to be due to the influence of the nerve-nucleus; the more complicated and, so to speak, purposive, the more likely is it to be traceable to the action of the corpus striatum or cerebral convolutions.

The ascertained facts with regard to the intimate association between certain areas at the surface of the brain and certain groups of muscular movements have a special importance in relation to the localisation of cerebral disease attended with convulsions. It will be recollected that irritation of each of these centres provokes specific combinations of convulsive movements; and these facts, together with Dr. Hughlings Jackson's, and (since his) other pathological observations on the same subject, demonstrate that we may in many cases determine the exact seat of cerebral lesion by paying minute attention to the details of convulsive attacks.

An important fact in connection with unilateral convulsive affections, such as chorea and epilepsy, due presumably to disease of the opposite cerebral hemisphere or corpus striatum, is that the convulsive movements are generally unilateral only in those parts, such as the arm and leg, which are chiefly paralysed in hemiplegia; while in those parts which are only slightly affected, or escape wholly, in hemiplegia, convulsive movements are not only present, but are associated with similar movements of the corresponding parts on the opposite side. This fact confirms Dr. Broadbent's hypothesis (already referred to) with respect to the more or less intimate connection subsisting between the corresponding nerve-nuclei of opposite sides. For that intimate connection which in hemiplegia would allow motor influences descending from the opposite healthy hemisphere to be in certain regions diffused horizontally, and thus to counteract paralysis, would necessarily equally allow abnormal motor impulses descending from the irritated hemisphere to influence in the same regions the motor nuclei of both sides, and thus to cause bilateral convulsions.

4. *Hyperæsthesia. Dysæsthesia*

Augmented or perverted sensibility has the same relation to the sensory part of the nervous system that spasms and convulsions hold to the motor, and indeed the two conditions are not unfrequently associated. Hyperæsthesia means strictly exalted sensibility—a condition in which the various organs of sense are more readily affected than they should be by impressions which are made upon them, or in which the sensorium is more appreciative than natural of the impressions which are conveyed to it from the organs of sense. Practically, however, exalted sensibility is scarcely, if ever, distinct from painful sensibility. The hyperæsthetic eye cannot bear bright light, the hyperæsthetic ear is affected painfully by powerful, high, or discordant sounds, the hyperæsthetic skin shrinks from the slightest pressure, or from mere contact. Hyperæsthesia in this sense is not uncommon; it is frequently observed in hysteria, sometimes in the early period of febrile disorders, occasionally in inflammatory and other affections of the central nervous organs. It is a common feature in hemiparaplegia, in which case not only is the paralysed side generally still sensitive, but its sensibility often becomes painfully acute; it is common, too, in inflammatory affections involving the skin.

Under the general term dysæsthesia may be included a large number of abnormal sensations, referrible to the ordinary sensory nerves, to the nerves of special sense, and to the sympathetic system, or, at all events, to the afferent nerves connected with the visceral organs. Among perverted sensations referrible to the skin may be included sensations already adverted to as frequently indicating the advance of anæsthesia, namely, numbness, sense of coldness, tingling, formication, and the like; as also itching, burning, cutting, stabbing, crushing, shooting, aching, constrictive, and other pains, which are so common, and arise under so many various conditions that it would be a waste of time to endeavour to enumerate them all. True neuralgic pains are usually of a shooting character, flash with momentary intensity along the fibres of the affected nerve, and occur in paroxysms composed of momentary shocks following one another in rapid succession. Other varieties of dysæsthesia are those which are manifested in relation to the visceral organs, among which may be included the 'want of breath' which attends asthma and cardiac disease; the agony of angina pectoris; painful thirst or craving for food; gastralgia, enteralgia; and various indescribable sensations referrible to different parts of the body, of which nervous and other patients complain, or which constitute many of the varieties of the so-called epileptic aura. Dysæsthesia of the organs of special sense may be indicated by the appearance of subjective phenomena referrible to these organs: of the eye, by the appearance of sparks or flames, or other objects, which may even present definite forms, be endowed with motion, and assume the visible attributes of living objects; of the ear, by the perception of sounds, such as humming, buzzing, singing, the ringing of bells, violent explosions, and even words and actual conversation; of the nose, by the perception of odours; of the tongue, by the perception of flavours.

### 5. *Influence of Nervous Diseases over the Nutritive Processes*

*a. Sympathetic system.*—There is no doubt that the sympathetic system is largely concerned in morbid processes. We know how importantly (according to the generally accepted view) constriction of the bronchial tubes is connected with asthma; what an essential part contraction of the vessels plays in the production of the phenomena of angina pectoris, and of the anæmia of the brain which, as a rule, precedes the epileptic attack; how largely dilatation of vessels is concerned in inflammation; and also that diabetes and various other disorders have been attributed to dilatation of the vessels of the liver or other organs, with consequent hyperæmia of these parts. We need not consider in detail the various pathological phenomena which are, rightly or wrongly, attributed to the influence of the sympathetic nerves. These, however, so far as the vessels are concerned, solely determine variations in diameter: if contraction of arteries or capillaries takes place less blood reaches the tissues, if dilatation takes place the tissues become hyperæmic. It need scarcely, perhaps, be said that the consequences of such contractions and dilatations of vessels will depend largely on the extent and duration of the spasm or relaxation, and on the anatomical arrangement of the vessels connected with the affected districts: that while in many cases nothing more than some temporary derangement of function occurs, in many cases the starved or over-fed tissues fall (as the case may be) into degeneration or necrosis, or into inflammation or pathological overgrowth, attended with more or less grave functional disturbance. It has already been shown, in our account of Raynaud's disease, that coldness and lividity, congestion and erythematous inflammation, gangrene, and extravasation of blood are among the recognised consequences of persistent spasmodic contraction of the smaller arteries.

*b. Cerebro-spinal system.*—Admitting fully the essential part which the sympathetic system plays in the regulation of the nutritive processes both in health and in disease, and admitting also the little obvious influence which the spinal system of nerves exerts over the same phenomena in health, it seems certain that it is to the spinal rather than to the sympathetic system that we must refer certain localised lesions which are apt to take place in the course of nervous disorders, and which we are now about to discuss. We refer more particularly to certain affections of the muscles, certain affections of the joints, certain affections of the skin and subjacent tissues, and certain affections of the viscera, especially the kidneys and bladder.

*i. Muscles.*—We have already shown that in many cases of motor paralysis the implicated muscles retain their healthy texture, their bulk and their contractility under the influence of stimuli, and, it may be, retain these qualities scarcely impaired for an indefinite period; only after a while wasting to a slight extent from mere disuse, and possibly undergoing some secondary degenerative change. Other cases of motor paralysis, however (cases for the most part of acute onset), are attended

with rapid loss of faradic contractility and concurrent acute wasting of the paralysed muscles. These consequences may follow : first, on lesions of motor nerves ; second, on affections of the cord ; and third, but much less frequently, on cerebral disease ; but they do not follow indifferently on all forms of disease or injury of these several parts. Charcot considers them to be due mainly to disease or injury causing irritation of the nervous tissue which is its seat, and especially to disease or injury involving the motor nerves or motor centres. If, therefore, muscular emaciation and loss of contractility be the consequences of lesion of a nerve, that lesion is probably not a clean cut, but the result of pressure, stretching, bruising, laceration, inflammation, or implication in some growth ; if they accompany spinal disease, they are due to disease, probably irritative, involving the anterior cornua, and particularly those groups of giant-cells which are in direct relation by means of motor nerves with the affected muscles. Others, however, regard them as the consequences simply of the interruption to the motor currents between the cord and muscles which disease or accident occasions. One of the most interesting examples of wasting of muscles due to disease of motor nerves is furnished by anæsthetic leprosy. Many different forms of spinal affection are apt to be followed by muscular atrophy. Posterior sclerosis, disseminated sclerosis, and disease limited in the first instance to the lateral white columns, may each, by horizontal extension, involve the anterior cornua at certain points, and so induce irregularly distributed atrophic changes of the muscles ; and similarly, caries of the vertebræ, fracture of the spine and tumours, may each of them, by pressure or otherwise, implicate the grey matter in their immediate vicinity, and hence cause atrophy of the muscles supplied by the nerves emanating from the seat of lesion. Further, diffused inflammation, and hemorrhage into the substance of the cord, both of which conditions may involve the central parts of the cord in a considerable length, may result in widespread muscular lesion. But the spinal affections which are the most common causes of muscular atrophy are those which induce infantile paralysis and equivalent conditions in the adult. In these the disease, which appears to be of an inflammatory nature, originates apparently in the groups of large cells occupying the anterior cornua, and even if distributed throughout the whole length of the cord may still be limited to them. When acute atrophy of muscles occurs as a sequela or consequence of cerebral disease, it is probably always directly referrible to some secondary descending lesion of the cord implicating the motor nuclei. Post-mortem examination seems to show that, in the particular form of wasting of muscles here discussed, the implicated nervous tissue from the seat of lesion downwards undergoes (mainly in its connective-tissue elements) inflammatory proliferation ; and that the initial change in the muscles is similarly an inflammatory hyperplasia of the connective-tissue elements and of the nuclei of the sarcolemma, inducing a kind of cirrhosis, to which the diminution in size of the muscular fibres is secondary. These fibres,

though gradually becoming more and more attenuated, seem rarely, if ever, to lose their striation or to become fatty.

ii. *Joints and bones*.—Affections of nerves are sometimes followed by inflammation of joints or periosteum, which may terminate in disorganisation and necrosis. But joint-affections are also occasionally developed, in the course of diseases of the cord or brain, in the members which are paralysed. Charcot divides these joint-affections into two groups. In the one the attack is acute or subacute, and attended with tumefaction, redness, and often more or less severe pain. In the other the attack commences suddenly, with diffused swelling of the limb, is attended with little or no pain, but involves the rapid erosion and disappearance of the cartilages and joint-ends of bones. The former of these affections has been met with in paraplegia from injury to the spine or from caries, and then most frequently in the knee. It has been observed also in hemiplegia, and mainly in hemiplegia due to softening; it then occurs usually in the joints of the upper extremity, which it attacks as a rule from two to four weeks after the occurrence of paralysis, and at the time when chronic contraction is taking place. This affection is essentially synovitis. The other form of the disease has been most frequently observed in persons suffering from locomotor ataxy, and for the most part at the onset of the symptoms of inco-ordination. It usually occurs in the knees, shoulders, or elbows, and is attended with much effusion into the joints, rapid destruction of the joint-surfaces, and not unfrequently dislocation. The processes here adverted to are not unlike those which occasionally attend rheumatism, and closely resemble those which are characteristic of chronic rheumatic arthritis. The diagnosis, however, between joint-affections of nervous origin and those due to rheumatic inflammation is generally easy, if attention be paid to the limitation of the disease to the paralysed limbs, and to the concurrence of other trophic changes belonging to the same class. It must be especially noted that the joint-affection is by no means unfrequently associated with rapid muscular atrophy, and there is ample reason for believing that it is due to affection of the same nerves and the same part of the cord whose irritation or destruction causes the muscular lesion.

Weir Mitchell has drawn attention to the frequent occurrence of spontaneous fractures of the bones in locomotor ataxy. And Charcot has more recently investigated the subject. He shows that such fractures, although they may occur in any bone, mainly affect the long bones, and more especially the femur at its neck. They are due to atrophic changes attended with diminution of the earthy salts, and are often preceded by symptoms of periostitis. We have already described the wasting and erosion of the phalanges which take place in the course of anæsthetic leprosy; and shall hereafter consider the arrest of growth which follows infantile paralysis, and the spastic hemiplegia of childhood.

iii. *Skin*.—Various inflammatory and other nutritive changes in the skin and subjacent tissues have been traced to affections of the nerves and nervous centres. It has long been recognised: that, after division of the

branches of the fifth pair distributed to the eye and conjunctiva, inflammation, leading to more or less rapid destruction of these parts, is apt to occur; and that in cases of paraplegia attended with total abolition of sensation, inflammation, ulceration, and gangrene are extremely liable to supervene in the paralysed parts. It has been proved, however, by experiment on the lower animals, and by the results of careful attention to patients suffering from such lesions, that these inflammatory changes are due not usually to the withdrawal of any direct conservative influence which the healthy sensory nerves exercise over the parts to which they are distributed, but to the fact that the loss of sensation prevents the sufferers from recognising the presence of mechanical irritants or other injurious influences, and so from avoiding or counteracting their operation. Various affections, however, more or less closely related to these in their characters, are undoubtedly referrible to the direct operation of irritative or paralytic affections of the sensory nerves, cord, or brain. The most important of them may be ranged under the heads of erythema, vesicular eruptions, bullous eruptions, atrophic changes, and gangrene.

Cases are not unfrequently met with in which the mechanical or other injuries to sensory nerves, not necessarily attended with anæsthesia, but often, as might be supposed, with neuralgia, are followed by erythematous redness limited to the area of distribution of the nerves, which redness may proceed to vesication, pustulation, ulceration, or gangrene. Such results have been observed in cases of tumour or inflammation involving the fifth nerve, and also in cases of injury or disease of certain of the sensory or mixed nerves of the arm or leg. One of the most interesting examples is furnished by herpes or zona, limited to the distribution of a single sensory nerve. Another example of great interest is afforded by anæsthetic leprosy—one of the special features of which affection is the excessive development of cellular elements in the course of the nerves, between the nerve-tubules. This overgrowth leads to the gradual destruction of the nerves and consequently to both anæsthesia and motor paralysis; but it leads also to atrophic changes in the muscles and bones and (what specially concerns us now) to erythematous patches on the skin, on which vesicles or bullæ become developed or which undergo atrophic changes, and in some cases to gangrenous destruction of the skin and subjacent soft tissues.

A peculiar atrophic alteration of the skin following injuries of the nerves of the extremities has been described, under the name of 'glossy skin,' by Sir James Paget and Dr. S. Weir Mitchell. In well-marked cases the skin becomes smooth, hairless, almost devoid of wrinkles, glossy, pink or ruddy, or blotched as if with permanent chilblains. The nails, too, become fissured and have a tendency to separate from their matrices. The skin thus altered is frequently the seat of an eruption having a close resemblance to eczema, and of a form of neuralgia which varies from the most trivial sense of heat to agonising pain. The skin, moreover, becomes extremely tender.

Trophic affections of the skin are equally apt to take place in connec-

tion with lesions of the cord. In locomotor ataxy, for example, according to Charcot, eruptions are occasionally developed, more especially during periods of exacerbation of the disease, and in connection with the occurrence of neuralgic pains; and he points out that the eruption is not unfrequently limited to the parts to which the suffering nerve is distributed. Among special forms of skin disease thus arising he mentions lichen, urticaria, zona, and ecthyma or impetigo; and we may add to the list erythema nodosum of unusual distribution. In this case Charcot attributes the cutaneous affection, as he does the pain, to the involvement, in the disease of the posterior columns, of the nerve-fibres passing through the outer part of these columns, previous to their emergence from the cord. Again, erythema in patches, which may go on to the development of vesicles (herpes), and thence to the formation of large bullæ (pemphigus), is not uncommonly a consequence of that affection of the membranes of the cord termed 'pachymeningitis,' which during its progress compresses and irritates the cord itself and the roots of the sensory nerves. A similar general development of bullæ is sometimes met with in vertebral caries. Erythematous, vesicular, or pustular eruptions are occasionally developed in hemiplegic patients upon the paralysed side of the body.

A peculiar affection of the feet, termed perforating ulcer, which occurs mainly in locomotor ataxy, and appears to be of nervous origin, is now generally recognised. It is for the most part met with in the neighbourhood of the metatarso-phalangeal joint of the big or little toe; is usually preceded by the appearance of a wart; and sooner or later forms a deep sinus connected with the joint or with bone. Its progress is very chronic. A similar condition has been observed in the hand.

The most important, and on that account the most interesting, of the cutaneous lesions consequent on paralysis are the patches of gangrene which are commonly known as 'bed-sores.' These are apt, of course, to form in many patients, whether paralytic or not, who are confined to bed, partly from the constant pressure to which prominent parts are under such circumstances exposed, partly from the effects of the patients' secretions, which accumulate beneath them, and in no small degree from the neglect of nurses. But there are certain paralytic cases in which bed-sores form with remarkable rapidity (in the course of two or three days, it may be, from the commencement of the illness), and this without exposure to undue pressure, or to the irritation of urine or fæces, and in spite of the most watchful care on the part of the attendants; moreover, the bed-sores appear on the paralysed part, and on that alone, even if the unparalysed parts have been specially exposed to pressure. The bed-sores here referred to commence as patches of erythema, with more or less inflammatory infiltration and congestion of the subjacent tissues, sometimes including the muscles and the bones. In a short time vesicles or bullæ appear upon them, and superficial sloughs form. These gradually extend in surface and depth, and may thus eventually occupy a wide area and involve muscles, bones, and even implicate subjacent cavities. Such bed-sores may occur either in hemiplegia, or in paraplegia, and on

any part of the paralysed surface, but they arise more especially on such parts as are exposed to pressure. In hemiplegia they rarely appear except about the centre of the buttock. In paraplegia they specially involve the sacral region, and are hence situated on a higher level than those occurring in hemiplegia, and occupy a more central and symmetrical site. Moreover, in paraplegia they are apt to appear also on the heels, inside the knees, and upon the hips. The form of hemiplegia which acute bed-sores tend specially to complicate is that due to hemorrhage. The spinal affections in which they more particularly occur are those in which inflammation or hemorrhage involves a pretty considerable extent of the central portion of the cord. They may hence follow fractures and other injuries of the spine, and exacerbations or acute complications of chronic diseases. The formation of these acute bed-sores must always be regarded as a phenomenon of serious import; but occasionally, of course, the morbid process becomes arrested, and convalescence may supervene.

The special seat in the cord of the lesions on which the various skin affections which have been enumerated depend has not been so accurately determined as the seat of those lesions which evoke affections of the muscles. There are good grounds, however, for the conclusion that the posterior cornua and central regions of the grey matter have the same trophic relation to the skin as the anterior cornua to the muscles.

iv. *Viscera*.—The visceral affections of chief importance referrible to spinal lesions are inflammations of the bladder and kidneys, with the discharge of purulent, bloody, ammoniacal, and fetid urine. In most cases of paraplegia these conditions are apt to supervene after a time in consequence of the constant retention of urine in the bladder, and the irritation to the mucous surface which results from its accumulation and decomposition. But there are certain cases of paraplegia, in which the occurrence of these phenomena is as early as that of bed-sores, and in which, indeed, they take place simultaneously. The change in the quality of the urine and the inflammation of the kidneys and urinary passages cannot then be explained by simple paralytic retention or by spontaneous decomposition of the urine; and there is consequently little doubt that they also are referrible to the direct influence of the diseased spinal cord.

#### 6. *Ascending, Descending, and Collateral Lesions.*

It is a fact of considerable importance, and one to which we have already more than once adverted, that circumscribed lesions of the brain, cord, and nerves tend to the production of degenerative changes either in the nervous tissue above them or in that below them, or in both; and, further, that in the case of the brain or cord there may be horizontal extension. Thus hemorrhagic or other destruction of some portion of the motor area of one of the cerebral hemispheres leads to the occurrence of degeneration, which, commencing at the seat of disease, gradually extends downwards in a band-like form along the motor tract, first involving the corresponding crus and anterior pyramid, and thence passing to the opposite side of the cord and downwards mainly along the posterior part of the

lateral white column, or that region which has already been referred to as the crossed pyramidal tract. In many cases also the fasciculus of Türk on the same side as the cerebral lesion presents degenerative changes. Again, when lesions occupy the lower part of the cord, they are apt to induce degenerative changes which gradually ascend in the posterior columns of the cord, mainly in those parts of them, the fasciculi of Goll, which lie immediately on either side of the posterior median fissure ; and occasionally also in the direct cerebellar tracts, and (there is good reason to believe) in certain tracts occupying the anterior parts of the lateral columns, immediately external to the anterior cornua (Gowers and Hadden). Further, lesions of intermediate regions of the cord are liable to be followed by both ascend-

FIG. 99.—Diagrams to show the parts affected in secondary ascending and descending degenerations. Areas of degeneration shaded with transverse lines.

A. Descending lesions from disease of left hemisphere of brain ; B. Descending lesions from disease of spinal cord ; C. Ascending lesions from disease of cord.  
(For further explanations see Fig. 92.)

ing and descending degenerations : the former, as in the last case, involving mainly the posterior columns ; the latter, as in the first case, the lateral columns and fasciculi of Türk. Occasionally also foci of disease involve secondary changes which extend from them in the horizontal direction ; and similar extension would seem now and then to start from either the ascending or the descending secondary lesions, so as to involve more and more of the thickness of the cord, and especially the anterior cornua and their motor nuclei.

When the anterior root of a spinal nerve is divided, its peripheral portion (at any rate its white substance) undergoes degeneration ; while if the posterior root be divided, all the peripheral part (that which still retains its connection with the ganglion) remains healthy, while that which enters the cord degenerates. It may, however, be observed that, consecutively to amputation of limbs, the large cells of the anterior cornua in relation with them have, after a considerable time, been found atrophic.

It is obvious that the various secondary changes above described, and others which occur but do not as yet admit of being referred to any general rule, must necessarily, in many cases, induce special clinical phenomena, complicating more or less seriously those due to the primary lesion.

## 7. Central and Reflex Consequences of Lesions of the Nerves

Not only are central lesions efficacious in the production of peripheral lesions, but lesions of sensory or centripetal nerves are capable of inducing central mischief, or, by reflex action, mischief in the area of distribution of

centrifugal nerves. It is thus apparently : that injury to sensory nerves induces that irritable condition of the spinal cord which forms the pathological basis of tetanus ; that intestinal irritation and the irritation of dentition cause convulsions in young children ; that certain uterine or ovarian conditions are instrumental in the production of the various psychical and motor phenomena which characterise hysteria ; that renal affections occasionally lead to paraplegia ; and that injury to the frontal branch of the fifth nerve is apt to cause amaurosis. Brown-Séguard indeed attributes to reflex influence almost all the consequences which are also caused by affections of the nervous centres ; among others, various forms of paralysis, anæsthesia, deafness, loss of taste and smell, convulsions, delirium, and coma, together with cutaneous eruptions and wasting of muscles. It is perhaps needless to add that he, as well as others, attributes many internal inflammations to the influence of irritation acting reflectorially.

### 8. *Headache*

Headache is a frequent attendant upon cerebral lesions, but it is still more commonly due to affections of remote organs, such as the stomach, or to neuralgic, rheumatic, or other such conditions. In whatever cause the pain originates, or in whatever part of the head the cause operates, it seems pretty obvious that the pain must be referred to the peripheral distribution of the sensory nerves which have their apparent origin at the base of the encephalon, and which are distributed to the integuments, bones, and membranes of the brain. Thus, some headaches are limited to one half of the forehead and probably to the corresponding eye—to the area of distribution of the first branch of the fifth—some occupy both sides of the forehead, some affect the vertex, some the occipital region. Other headaches, again, appear to occupy the temples, and shoot from one side to the other, others are confined to the neighbourhood of the ear, and others seem to be generally diffused. Headaches vary in character, and are variously described. Sometimes they are shooting, sometimes aching, sometimes throbbing, likened sometimes to a weight upon the top of the head, sometimes to a sense of constriction. They are not unfrequently associated with intolerance of light and sound, visual spectra, tinnitus aurium, vertigo, nausea and sickness, drowsiness or wakefulness, and sometimes (even if the affection be superficial and wholly independent of brain disease) with delirium. It is in most cases exceedingly difficult to refer headache to its proper cause, unless our diagnosis be aided by the presence of distinctive associated phenomena. Thus pain, almost accurately resembling in all its characteristics that of megrim, may be induced by the simple pressure of an unyielding hat upon the frontal branches of the fifth pair, and immediately cured by the removal of that pressure ; rheumatic neuralgia of the forehead, from simple exposure to a blast of cold air, is not unfrequently attended with a peculiar sense of drowsiness ; and in either case the pain may be so intense and so distracting as to lead the patient or his doctor to suspect serious disease of the internal parts. Dr.

Hughlings Jackson remarks that frontal headache is generally referrible to abdominal affections, headache at the vertex to cerebral disturbance, and occipital pains to disorders of the circulation, and more especially to anæmia. However that may be, it is certain that pain due to cerebral disease may, especially in the case of cerebral tumours, be referred to any part of the head, and that it may exactly simulate pains which are of less serious origin. It may be slight or intense, continuous or paroxysmal, and may be attended with tenderness of the scalp, or other of the symptoms already referred to as frequent accompaniments of headache. When the pain is intense, and especially if it be paroxysmal, it frequently causes the patient to scream out, and to support his head with his hands. The most intense pain, which is then usually strictly limited as to its seat, is induced by the pressure of intracranial tumours or abscesses upon sensory nerves.

### 9. *Vertigo*

Vertigo, or swimming in the head, is that condition in which a person suffers from a sense of failing equilibrium, of falling or of rotating, and in which not unfrequently surrounding objects appear to swim or oscillate before his eyes. It has been attempted to distinguish between that form of vertigo in which the patient refers the vertiginous phenomena to his own person, and that in which he refers them to surrounding objects. The distinction is, however, obviously inadmissible. Vertigo may vary from a mere uncomfortable sense of oscillation, such as one feels on landing after a sea-voyage, to a condition in which the patient is quite unable to maintain his equilibrium, and either falls to the ground, or is compelled to support himself by clutching some fixed object. It may be momentary or of long duration, and in the latter case is commonly attended with exacerbations. It is generally more pronounced when the patient is standing or walking, but may come on while he is lying down, and even has his eyes shut. The proximate cause of vertigo is probably multiform. Vertigo is often, and probably accurately, referred to variation or disturbance of the cerebral circulation; in proof of which view it may be observed that it attends syncope, anæmia, and loss of blood on the one hand, and cerebral congestion and inflammation on the other. It is a consequence of an unhealthy condition of the blood, or of the presence in it of poisonous matters; as appears from its frequent occurrence in inflammatory diseases and in the specific fevers. It attends epilepsy, eclampsia, and organic lesions, such as effusions of blood and tumours. It is frequently of eccentric origin, referrible, for example, to dyspepsia or other functional derangements of the stomach. Physiological experiments have, as we have already observed, demonstrated that the cerebellum is the centre of equilibration, and that injury or irritation of this organ or of the parts immediately connected with it, such as the pons Varolii, corpora quadrigemina, or crura cerebri, in the lower animals, is followed by vertiginous movements. It is probable, therefore, that in the human being vertigo is referrible in large proportion to functional disturbances and organic

lesions of the same parts. It is certain that affections of the cerebellum are generally if not always attended with failure of the power to maintain equilibrium. Affections of the eye and ear, and even of the spinal nervous system, are also capable of causing vertiginous phenomena. In the case of the eye, vertigo depends, for the most part, on affections involving the muscles, such as loss of power in one or more of the recti of one eye, in consequence of which a convergent or divergent squint is produced; or on the presence of nystagmus. Vertigo referrible to the ears is usually associated with deafness, and immediately due, according to Ménière's researches, to disease of the semicircular canals, injury to which has been shown, by experiment on the lower animals, to be followed, equally with injury to the crura cerebri, by vertiginous movements. In reference to affections involving the spinal nerves, it may be observed that the inco-ordinate movements of locomotor ataxy, and the oscillating movements of disseminated sclerosis and of paralysis agitans, are not unfrequently attended with the subjective phenomena of vertigo, especially if their influence be not counteracted or neutralised by sight or hearing. Vertigo is frequently associated with headache, functional disturbance of the eyes and ears, sickness, and other phenomena. The recognition of the exact cause of vertigo in any case must be based less upon the simple vertiginous phenomena than on the accompanying symptoms.

#### 10. *Paralytic Affections of Speech. (Aphasia. Aphemia. Amnesia)*

We employ the above terms in their widest sense, and as including, therefore, not merely defects referrible to, or manifesting themselves in, the organs of articulation, but defects relating to reading and writing. Paralytic affections of articulate speech may be divided into four classes;—first, that in which the motor nerves of the organs of speech are paralysed in a greater or less degree, and where, therefore, the defect of speech is simply the result of inability to use these organs; second, the class in which the co-ordinating centre of the movements of articulation is affected, and where the patient, having complete control over the movements of his lips and tongue for other purposes, is yet unable to utter articulate sounds; third, the class in which the impairment of speech is central, where there is loss of memory of words, or *amnesia*, and other losses of mental attributes; and, fourth, a complex class, including all those cases in which the conditions characteristic of the second and third classes are combined.

*a.* The *first class* comprises a well-defined but rather wide range of cases, among which may be enumerated those of right or left hemiplegia, general paralysis of the insane, locomotor ataxy, disseminated sclerosis, chorea, glosso-laryngeal palsy, and lesion of one or more of the motor nerves of the organs of speech. In left hemiplegia and in paralysis of one portio dura or hypoglossal, the defect of speech is often scarcely appreciable, and rarely amounts to more than a little thickness of utterance. In general paralysis there is usually a little tremulousness of the tongue and lips when the attempt to speak is made, a little hesitation

and thickness or inexactness of utterance, which becomes especially marked when the patient speaks with vehemence. In locomotor ataxy and disseminated sclerosis the defect of speech may present some degree of variety: in some cases there is more or less slowness and tremulousness; in others the slowness is attended with exaggerated efforts on the part of the lips and tongue to effect their purpose; in others the syllables are unnaturally divided, and there is a tendency, as it were, to scan the sentences; but in all, even though separate letters may be accurately enunciated, the more complex their combination in words the more clumsy and inexact does their pronunciation become, and the latter parts of long sentences, or of a sustained conversation, always contrast unfavourably in these respects with the beginning. In glosso-laryngeal paralysis, the early stages of defective articulation resemble those observed in general paralysis; but gradually the lips, tongue, and soft palate lose almost entirely their capacity for movement, and the patient loses not only the power of articulation, but that of retaining the saliva in his mouth, and that of swallowing.

*b.* The *second class* of cases corresponds to the group to which Dr. Bastian endeavours to limit the use of the word *aphemia*, adopting the word from Broca, who, however, has employed it in a different and far wider sense. Typical cases of this kind are very rare. In them, patients recovering from an attack of unconsciousness are found to be entirely speechless and to remain speechless for days, weeks, or even months, notwithstanding that they may have regained the use of every other faculty which might be supposed to have any, the remotest, connection with speech: that is to say, notwithstanding that they can hear, understand everything that is said to them, read, converse by means of writing, and use the lips and tongue with the utmost precision for every purpose excepting speech. Now in such cases as these it is obvious that the patient retains all his mental faculties, and that he thinks (as is probably usual) with the aid of words, which he still retains the power of expressing by means of writing; but which he cannot utter, not because he has lost the use of his muscles of articulation, but because the wish to speak does not evoke the combined automatic movements on which speech depends. In ordinary conversation the words which express our thoughts flow automatically from our lips; the complicated combinations of movements on which their utterance depends are executed momentarily and with the utmost precision, without any attention whatever being, as a rule, bestowed upon the movements themselves.

Looking to the extreme complexity of these movements, it seems certain that that part of the brain in which words are transformed into ideas, and are revived in thought, acts, in the process of transforming them again into articulate speech, upon the centres of origin of the various nerves of speech, through the intermediate agency of a special co-ordinating centre. This centre is probably situated somewhere in or below the corpus striatum; and within it, on the receipt of the message from above, the various telegraphic communications with the nerve-origin below are automatically so manipu-

lated as to cause, through these latter, the organs of speech to execute the necessary combined movements. Words are practically innumerable. The elementary articulate sounds, however, which by their combination produce articulate language, are probably less than fifty in number, and this comparatively small number therefore also represents all the groups of simultaneous combined movements which the tongue and lips can be called upon to execute. It seems probable, partly on these grounds, partly from the consideration that language (apart from the mere mechanism by which it is uttered) is a mental function, and partly from the consideration that the function of a co-ordinating motor centre is to regulate or combine groups of movements, that the duty of the assumed co-ordinating centre of speech must simply be to preside over that essential but comparatively subordinate department of speech which consists in the production of the elementary articulate sounds. If this view be correct, it is easy to understand how some lesion involving this centre or cutting off the direct communication, either between it and the intellectual centre of language above, or between it and the nerve-nuclei below, might result in dumbness, while at the same time the command of language might in all other respects be retained perfectly, and the power of executing the most delicate movements with the lips and tongue remain intact. It is easy also to understand how, in such cases as this (considering that all articulate sounds are merely the results of certain mechanical arrangements of the speech-organs), the patient who has lost the power of speech might be taught to copy these mechanical arrangements, and thus again to speak, exactly as deaf-mutes are taught. The morbid anatomy of this class of cases has not yet been investigated. The patients in whom aphemia has been observed have had fits, epileptic or apoplectic, from which they have recovered with or without temporary paralysis.

*c.* In the *third class* of cases there is *amnesia*, or loss of memory of words. In typical examples of this kind the patient, with perfect power of utterance, is yet incapable, from want of words, of joining in conversation; with perfect vision he is unable to read even to himself; and with (it may be) entire command over his arm and hand, he cannot make himself understood by writing, or even write. In most if not in all of these cases, however, not merely is there forgetfulness of words, but there is more or less inability to recall facts, to concentrate the thoughts, and to pursue any train of reasoning. An amnesic patient, when he attempts to speak, commences perhaps with one or two words correctly uttered, then hesitates for a word, probably uses a wrong one, notices that he is wrong, tries to correct himself, perhaps repeats the words that he first uttered, stumbles a little, and then, with a gesture of annoyance, comes to a stop. If his speech be carefully observed, it will generally be noticed that his vocabulary is limited to a very few words, and that he tends to repeat certain of these, and especially to repeat certain combinations of them; and indeed he often appears to recall phrases more readily than single words. If asked to name even the most common thing he fails in very large proportion, and fails probably to remember words which he has been taught to utter only a minute or two previously.

Yet he seems to understand everything that is said to him ; he at once distinguishes the right name from the wrong when submitted to the test ; and he can articulate readily every word which is dictated to him. It is very interesting to note that uttered words entering by the ear are by a voluntary effort at once and perfectly reproduced by the organs of speech, and at the same time recall for the moment to his mind the ideas which properly attach to them. Such a patient may often be seen with a newspaper or book, over which he pores as if he derived the greatest interest from its perusal ; but on asking him to read aloud he will probably indicate his inability to do so, and not even make the attempt ; or possibly he may pick out a word here and there which he recognises and which he pronounces with more or less approach to accuracy. It might be supposed, although he cannot translate written into vocalised words, yet that written words convey to his mind through the eye their proper meaning, and that hence he really understands what he reads. This, however, is generally not the case, for if he be examined by leading questions he fails to show that he has any knowledge of what he seems to have been reading about. He will, however, not unfrequently point out here and there words, or phrases, which he recognises and perhaps utters. He seems, indeed, much in the condition of a child poring over the pages of a book written in a foreign language, which he has just begun to learn. If now asked to name letters he probably fails, just as he previously failed with words ; and, again, if asked to point out letters as they are named to him, his inability is equally marked. In fact, just as he has forgotten the names of things he has forgotten the names of letters, and consequently their value ; and he fails, partly on this account and partly from the complexity of the mental process which it involves, to attach any sound or any meaning to the various combinations of letters which stand for words. When he recognises printed words, it is probably as a whole that he generally recognises them : thus, he will sometimes point out his own name, though unable to point to, or designate, a single letter it contains.

A similar difficulty exists in regard to writing. If his hand and arm be not paralysed, or only slightly thus affected, he can execute all accustomed delicate movements with them, and indeed can employ the hand as a mere machine just as well, probably, as ever he did. If he could draw, he can probably still draw, and he can copy the forms of geometrical figures and therefore the forms of letters. He can write and print from a copy. If, however, he tries to write (and he is not unfrequently fond of writing) he either makes a series of unmeaning up and down strokes, manifesting even here a dim recollection of the art of writing, or he begins a word, perhaps his own name, correctly, and after writing a letter or two repeats them and then stops, or passes on into unmeaning strokes. If words are dictated to him he writes them even more incorrectly than those which he writes voluntarily, and probably writes letter-characters which are dictated to him as faultily as words. Yet not unfrequently, if he be set to copy from a printed page, he will translate the printed words (letter by letter) into their written equivalents as well and as quickly

as if he were in perfect mental health, and this without being able to name or to understand the printed words and letters, or those which he himself forms. It is curious to observe here the correspondence that exists between the eye and the hand: the patient sees the printed word, and by an effort of the will reproduces it automatically in written characters; yet neither the word he sees, nor its written equivalent, nor the act of writing it, brings to his mind, even for an instant, any glimpse of its meaning. An amnesic patient who is unable to write from dictation will often put down figures from dictation, and, further, perform simple arithmetical sums upon a slate with tolerable correctness. He may even perform sums in addition of money; and very curiously he will sometimes, while adding up, miscall the figures which he writes down correctly.

Now the degree in which any one or all of the above peculiarities may be present in any case varies of course within wide limits; and so also does the degree in which the patient's memory of facts and power of concentrating his thoughts, and of reasoning, are retained. But the deficiency of his mental powers is not to be measured by the degree of his loss of memory of words. Many of those patients in whom the amnesic condition is extreme take such a lively interest in all that is going on around them, play at simple games of skill so cleverly, are so quick in their movements and in the use of their senses, and display such quickness of perception, that they obviously possess considerable intelligence. We are apt indeed to give them credit for much more intelligence than they really possess. It seems probable that, in proportion to their inability to recall facts and words by voluntary effort, they live more and more, as it were, in the objects which present themselves to their senses, and in the evanescent ideas which they evoke.

But many amnesic patients present peculiarities which do not quite accord with the above description—these peculiarities being due either to the degree in which the patient is affected or to the fact that other forms of sensory, motor, or mental derangement are superadded. In some cases the aphasic condition is revealed only by the occasional misuse of certain words, or by the omission of certain words or letters in speaking or writing, or by the occasional employment of wrong endings, or beginnings to words, or by the transposition of syllables or letters, or by the use for the word intended of some other word having a phonetical relation with it, or some analogy to it either in its meaning, in its appearance, or in the ideas it evokes; in other cases the patient's vocabulary is limited to one or two sounds or words, such as 'yes' or 'no,' or to a phrase or two, such as 'damn it,' or 'can't afford it,' which he utters whenever he makes the attempt to speak, and sometimes without appearing to recognise that his language is in any degree peculiar. In other cases the patient does little more than repeat words which are dictated to him, and these he repeats over and over again until a newly dictated word displaces the former one from his memory. In other cases, again, he makes inarticulate sounds, which he utters volubly and with emphasis, and which, if carefully

attended to, seem divided into lengths. These sounds, indeed, may have some obvious phonetic relation with words, and as the patient's condition improves become resolved into articulate speech. It may be added that amnesic patients not unfrequently utter an unexpected oath or phrase under the influence of emotional excitement, just as paralysed patients under similar circumstances are apt to move limbs over which they have no voluntary control; and, further, that amnesic patients who have but few words at their command, when asked to repeat from dictation things that they have learnt, such as 'the Lord's Prayer,' the numerals, or the alphabet, will often, instead of repeating the word or sentence actually dictated, utter the word or sentence which immediately follows, and possibly continue their recitation until they become confused and mumble unintelligibly, or repeat themselves. It is this third group of cases, together with the fourth group (to be considered presently), to which the investigations of M. Broca and others chiefly relate. It is in these cases that there is almost invariably right hemiplegia dependent on some lesion of the left cerebral hemisphere, occupying, roughly speaking, the district which the left middle cerebral artery supplies, namely, the corpus striatum and the wedge of nervous substance extending outwards, towards, and including in its base, the island of Reil with some of the neighbouring convolutions—more precisely (according to M. Broca) the posterior third of the third frontal convolution. It is this district in which the effects of cerebral embolism are most frequent.

*d.* The *fourth group* of cases includes all those in which amnesia is associated with aphemia, or with both aphemia and paralysis of the organs of speech. These cases are very numerous, and present great varieties of symptoms, according to the degree in which each of the above-mentioned conditions is present, absolutely or relatively. In typical cases of this class the patient, after an attack of right hemiplegia, loses absolutely the power of speech, or at most utters some one or two inarticulate sounds, and perhaps has some difficulty in using the tongue and lips; but he apparently understands everything that is said to him, and, when asked to point out words and letters on a printed page, probably points them out correctly. So far the symptoms are those of aphemia. But presently the patient gradually or suddenly recovers the power of articulate utterance, and it is then found that he is suffering from amnesia in addition to aphemia, that he has in a greater or less degree forgotten the names of things, perhaps his own name.

In conclusion it may be suggested that it seems convenient still to employ the word 'aphasia' in that general sense in which it has been used by Trousseau, as inclusive of all difficulties of speech which come under the second, third, or fourth of the above groups; and that inasmuch as the aphasic condition thus defined includes two perfectly distinct clinical phenomena, which, though often combined, may exist separately, it seems also convenient to have a distinct name indicative of each of them, and applicable to those cases in which one or other of them occurs separately. The terms 'aphemia' and 'amnesia' may be thus employed.

We may here call attention to the facts: that articulation and phonation are distinct elements in spoken language; that phonation in some degree survives in all cases of aphasia, and that not unfrequently aphasic patients who can utter only one or two words can yet hum tunes with facility; and that loss or impairment of phonation is usually the result of disease involving directly the nerves of the intrinsic muscles of the larynx, or of hysterical and other such functional disturbances.

### 11. *Stammering*

This affection of speech comes on usually in childhood, but occasionally at later periods of life, probably in consequence of some sudden impression either on the general system or on the nervous organisation. It is occasionally a symptom of general paralysis of the insane and of locomotor ataxy, and now and then comes on temporarily in hysteria, chronic plumbism, and other disorders. It is much more common in males than in females. It is characterised essentially by the occurrence of a sudden hitch in the act of speaking, a momentary or longer arrest in the flow of sounds.

It is generally held that it is at the explosive consonants, *b, p, d, t, k*, and hard *g*, that the sufferer comes to grief; that the continuous consonants are for the most part pronounced readily; and that the vowels are freely uttered. This statement, however, by no means expresses the whole truth in relation to the matter; for a careful examination of a series of stammerers will show that, while some will perhaps halt especially at the labial, others especially at the lingual, and others especially at the guttural explosive consonants, all (or nearly all) are liable at times to stumble, not only at any one of the explosive consonants, but even at those which are continuous, and some even will manifest an impediment in the utterance of simple vowels. When the check occurs at the lips, the evolution of the labial sounds is arrested by a sudden spasmodic closure of the mouth; when at the point of the tongue, this gets fixed in the position belonging to the utterance of lingual sounds; when at the base of the tongue, this becomes spasmodically approximated to the palate. In some instances, and especially when the vowel sounds are implicated, the spasm takes place at the glottis. And not unfrequently the stammering, whether occurring in connection with vowels or consonants, is due to a sudden inspiration. But whatever part the spasm may affect primarily, the arrest may consist either in a sudden, simple, more or less prolonged spasm, or in a series of such spasms in rapid sequence, during which the literal sound undergoes more or less frequent repetition. And, further, there is generally a tendency, especially if the spasm be prolonged, for a greater or less number of other groups of muscles to be involved. So that, for example, if the spasm commence at the base of the tongue, we may find in some cases that the mouth opens widely, and remains in that position, the muscles of expression work convulsively, the glottis contracts, respiration becomes

arrested, and, finally, spasmodic movements of remote parts become also excited.

The differences presented among stammerers are, no doubt, considerable, and, in a certain degree, important; but the resemblances are far greater than the differences, and there can be little doubt that the pathological explanation is the same in all. Speech, even in its mechanical details, is a very complicated art; it requires for its perfect performance not only that the respiratory apparatus, the laryngeal instrument, and the organs of articulation shall uniformly co-operate with the greatest nicety under conditions that are ever varying, but, as regards the last organs especially, that they shall pass from one arrangement to another arrangement with unfailing ease, certainty, and rapidity. It is generally in connection with complicated, rapidly varying muscular combinations, which are rendered easy of performance, and more or less automatic by long practice, that momentary spasms or hitches are liable to occur and mar the performance.

It is thus, as we shall hereafter show, that occasionally the swordsman's arm becomes arrested in some particular attitude, the pianist has to give up his playing because of some recurring sudden inco-ordination, and the scribe especially is seized during his work with momentary spasm, or cramp, which checks or spoils his writing. And it is, doubtless, thus that spasm in the utterance of articulate language takes place, and that this spasm (although it may commence in any of the three component mechanisms of speech) almost always begins either in the organs of articulation themselves, or in connection with the mutual co-ordination of the different factors of speech (respiration, phonation, and articulation), and at the commencement of words and syllables.

It has been asserted that stammering does not occur when the sufferer whispers, or when he sings or intones. Neither of these statements, however, is accurate. Whispering is frequently attended with stammering, and, although the singing voice is usually free from it, it undoubtedly sometimes suffers. Stammerers, as a general rule, are capable of enunciating all literal sounds and all combinations of sounds; and there are times at which even the worst stammerers speak well. The defect is generally aggravated by nervousness, exhaustion, bodily illness, and temporary affections of the organs of speech.

Stammering is rarely amenable to direct medical or surgical treatment. It may, of course, be cured in certain cases by curing the hysteria or other such condition on which it depends, and it may be benefited in others by remedying the conditions which are causing temporary aggravation. For confirmed stammerers there is little or nothing to be done, beyond making them practise in private the articulation of the sounds or combinations of sounds which are specially difficult to them; teaching them to speak slowly, deliberately, and even with exaggeration of distinctness, and, instead of making persistent efforts to speak when the impediment occurs, to halt for a moment, and recommence; and encouraging them to throw off shyness and nervousness. Some persons have learnt

to overcome the impediment by intoning their speech. The cure, which is generally possible, depends upon the patient himself, and can only be attained by long-continued daily practice in speaking and reading aloud.

In connection with this subject it may be worth while to advert to the fact that many persons appear to be incapable of pronouncing certain letters, more especially, perhaps, *l*, *r*, *th*, and *s*—a defect dating from early infancy. In some cases, no doubt, such mispronunciations may be connected with some faulty conformation of the organs of articulation. But in the great majority it is simply the result of defective education or of the perpetuation of infantile blundering; and in nearly all it is quite possible for the sufferer to learn to pronounce correctly the sound which he has hitherto failed to utter by being shown how to put his organs of articulation into the position on which the correct utterance of the sound depends, and by persistent practice. It must be admitted, however, that just as persons who have never learnt to aspirate in early life rarely acquire facility in aspirating in after-years, so in these other cases of early defective literal utterance it is probable that facility of correct pronunciation will never be acquired.

### 12. *Mental and Emotional Disturbances*

It may be pointed out, in conclusion, that all forms of mental disorders are apt to attend not only brain-diseases, but a large number of affections in which the brain is only secondarily or remotely implicated. This subject is much too vast to admit of separate discussion here. It may, however, be observed that patients may suffer in feeling, intelligence, and will, either conjointly or separately, and that these may be exalted, perverted, or impaired. Thus, as regards feeling, he may be excited (angry, boisterous, merry), depressed (melancholy, anxious, fearful), or suspicious, mischievous, or sullen; as regards intelligence, his ideas may flow rapidly and with vivacity, he may have delusions, his reasoning powers may be perverted or impaired, his memory may fail, or there may be incoherence or general mental imbecility; and, as regards will, he may show abnormal obstinacy or tenacity of purpose, extreme vacillation, or utter listlessness and apathy or incapacity for exertion. The various forms of delirium—the low muttering, the busy or garrulous, and the maniacal—are all common in different forms of disease. Insanity in all its varieties is apt to attend or supervene upon a large number of acute or chronic disorders, whether these affect the brain or other parts. And, lastly, coma—the abeyance of all mental phenomena, the condition in which the patient lies as in a profound sleep and insensible to every external influence—if not the primary disorder, constitutes the common fatal termination of most of the other mental affections which have been enumerated.

### C. *Electricity in Nervous Diseases*

The employment of electricity is so important not only in the treatment of nervous diseases but for the purposes of diagnosis, that a few remarks in reference to its mode of application and uses will not be out of place.

Two forms of electricity are employed in medicine : one the *continuous* or *galvanic* current, the other the *induced* or *faradic* current. The former is the kind of electricity which is developed by chemical decomposition, and is usually obtained from one or more similar cells, arranged in a series or circuit. For medical purposes a battery of from twenty to fifty cells is usually employed. The latter is the kind of electricity furnished by magneto-electric and other induction machines. The *galvanic current* is characterised : first, by constantly flowing in one direction, namely, from the positive pole or rheophore to the negative pole ; second, by its comparatively low intensity, and considerable quantity—its intensity, however, depending on the number of cells employed, its quantity on the size of the elements ; third, by its possession of powerful chemical and thermal properties which are specially observable at the point of application of the negative rheophore ; and fourth, by its comparatively little influence in causing muscular contraction. The *faradic current* is of instantaneous duration, occurs only at the moment of making or breaking contact, and takes place alternately in both directions. It is remarkable for its high intensity, and for the powerful effect it has in causing contraction of muscles and in acting on motor and sensory nerves. But it has no thermal or chemical influence whatever.

The rheophores, or instruments by means of which electricity is applied, are of various kinds ; but they should always be furnished with insulating handles, so that they may be freely and safely manipulated by the operator. The larger ones generally consist of a sponge fixed in a metallic cup ; the smaller ones are usually ovoid metallic knobs covered with wash-leather.

If the electricity is to be limited in its action to the skin the rheophores must be used dry, and it is well even to dust the skin with a little dry powder ; but if, as is usually the case, muscles or nerves are to be acted on, they should be well moistened with hot salt and water, as also should the surfaces to which they are applied.

There are three different ways in which galvanism or faradism may be used to influence muscles. First, superficial muscles may be acted upon individually by placing the rheophores immediately over the belly of each muscle which it is desired to affect. In this case the rheophores should always be situated within a short distance of one another. Second, one rheophore may be applied over the trunk-nerve leading to a group of muscles, and the other successively over the different muscles supplied by this nerve, each of which will thus in turn be caused to contract. Third, one rheophore may be fixed on some indifferent part of the surface, as for example on the nape of the neck or the sternum, while the other is placed over the nerve leading to the individual muscle or group of muscles which it is intended to influence. By this method, which is sometimes termed the indirect method, many deep muscles which could not otherwise be reached may readily be made to contract. It need scarcely be said that the successful employment of this method requires accurate knowledge of the situations at which muscular nerves are most accessible. In this case the first rheophore should be of large size, but the second or that to be

applied to the nerves should be small and ovoid. In employing faradism the positive pole, or anode, is usually applied to the indifferent part of the body, the negative pole, or cathode, to the nerve or muscle to be stimulated.

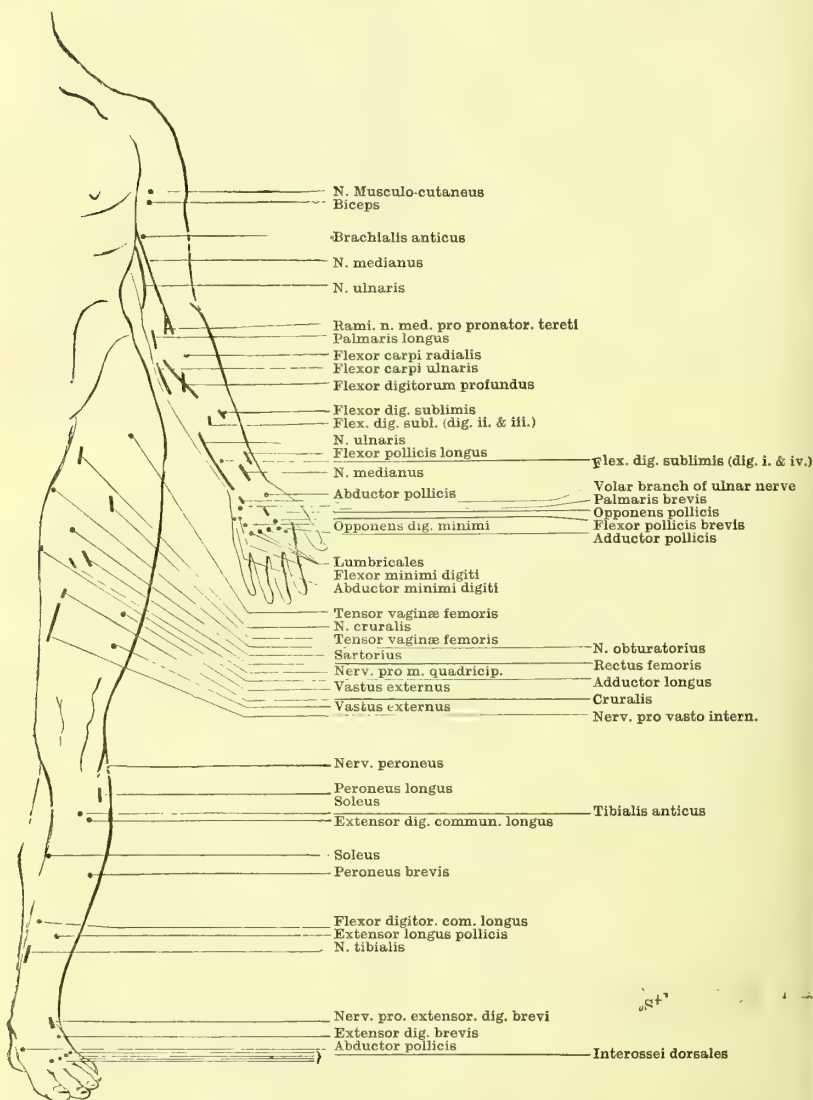

FIG. 100.—Ziemssen's motor points on front of arm and leg.

In using galvanism the relative positions of the rheophores must be determined by the special conditions of the case.

The same methods of procedure may be employed for galvanising or faradising nerves.

In employing electricity for diagnostic purposes it is important:—first, that if possible corresponding healthy and diseased parts in the same individual should be compared; second, that the patient should be as

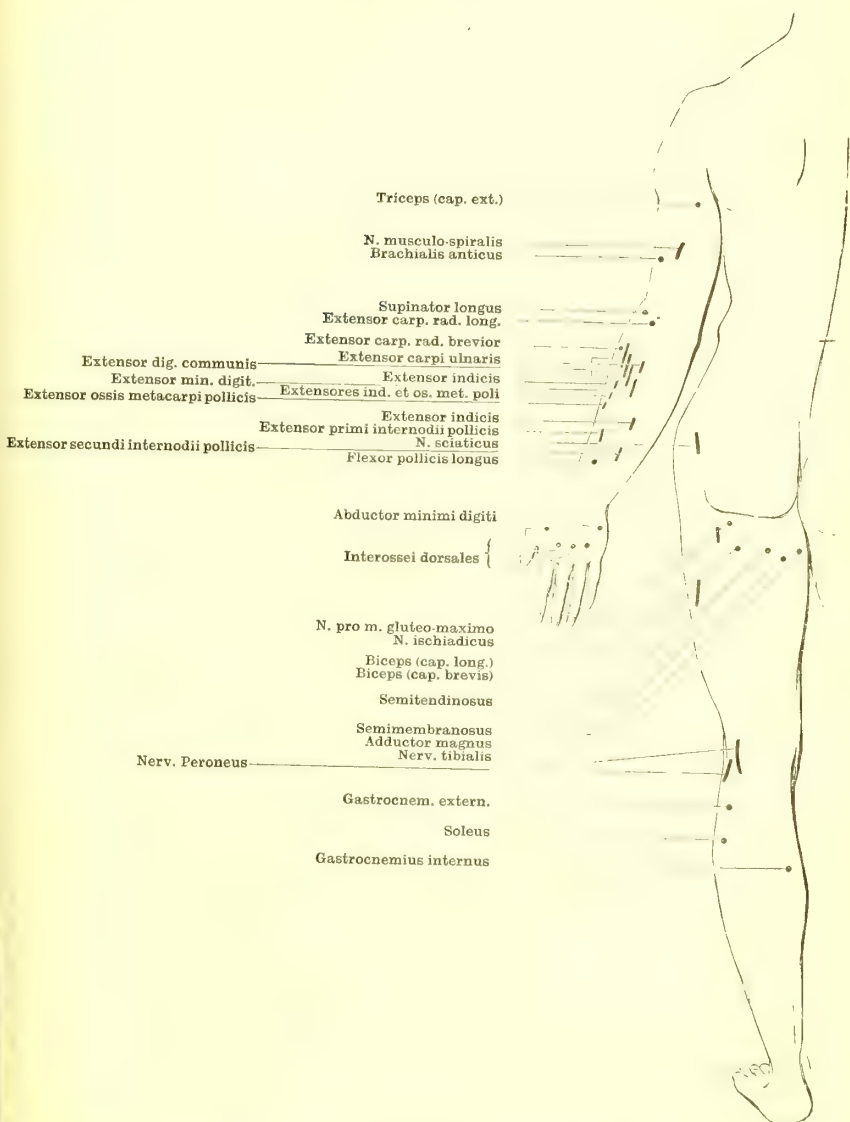

FIG. 101.—Ziemssen's motor points on back of arm and leg.

far as practicable at absolute rest, and especially that the parts to be examined should be placed under exactly similar conditions; third, that the rheophores should be the same and at equal distances apart, and the

strength of the current identical, in each parallel series of observations ; and fourth, that as a general rule, in testing the diseased side, the feeblest current capable of affecting the healthy side should be employed.

Faradism has, as has been pointed out, a very powerful influence in causing continuous contraction of healthy muscles, the intensity of the contraction being proportionate to the intensity of the current employed. Galvanism in the same case causes contraction only at the moment of making or breaking, or in other words, of opening or closing, circuit. Its peculiar properties are best manifested when the interruptions are slow. Its effects vary in health both with the strength of the currents employed, and with the relative positions of the rheophores. Thus the anode, or positive pole, causes contraction chiefly on making circuit ; the cathode, or negative pole, causes contraction chiefly on breaking circuit ; and, further, the cathodal stimulus is greater than that of the opposite pole. But with a feeble current the anode causes no contraction at all, while the cathode causes contraction only on closure ; with a medium current the anode causes feeble contractions both on opening and on closing, while the cathode causes strong contraction on closure, but still none on opening ; and lastly with a strong current the anode evokes marked contractions at both times, while the cathode produces tetanic spasms on closure and feeble contraction only on opening.

The effects of electricity on paralysed muscles are variable. In hemiplegia there is no necessary change in this respect ; but in the early period, and at times when inflammation or other irritation is present, there is often some increase of reaction to both forms of stimulus ; while later, sometimes from mere disuse, sometimes in connection with secondary degenerative nervous lesions, this undergoes diminution. In paraplegia the electrical phenomena are much the same and obey the same rules, but here both faradic and galvanic irritability are in the early stage of the disease more commonly and more markedly increased than in hemiplegia.

In destructive lesions of motor nerves or of their nuclei of origin the consequences which ensue are remarkable and for the most part distinctive.

At first the reactions of the paralysed muscles both to faradism and to galvanism are normal. Then both varieties of irritability undergo some degree of diminution. At the end, however, of a week or ten days, faradic contractility diminishes considerably, and in the course of a week or two more probably becomes wholly lost. But while faradic contractility is disappearing, galvanic contractility increases, and in the course of a short time the affected muscles probably react to a current half as strong as that which is required for producing the same effect on the healthy muscles. Moreover, the contractions, instead of being rapid as they are in healthy muscles, become slowly developed, and of long duration. Further, a direct reversal takes place in the relative effects of the anode and cathode ; there is a gradual and strong increase of the anodal closing contraction, which soon equals or exceeds the effects of the cathodal closure ; and, on the other hand, the cathodal opening contraction increases more than the anodal opening contraction, and soon equals it

or surpasses it. At a late period the response of the diseased muscles to galvanism in its turn diminishes and disappears.

As regards nerves it appears that for a few days after their division there is sometimes a slow increase of both galvanic and faradic irritability. But soon gradual decrease takes place; and finally, at the end of a week or two, all irritability ceases to both forms of electricity. The electric irritability of nerves once lost is very slow to return, and it is an interesting fact that the recovering nerve sometimes allows the passage of the mental stimulus while it is still wholly irresponsive to electricity. It is suggested by Erb that this phenomenon is dependent on thickening of the neurilemma. Onimus considers that the failure of paralysed muscles to respond to faradism while they still react to galvanism is due to changes having occurred in the intra-muscular nerves. It need scarcely be added that when motor nerves have lost their electric irritability, it is impossible to stimulate muscles by the indirect method.

The condition above described, in which faradic irritability is lost and galvanic irritability is increased and altered in quality, is called by Erb the 'reaction of degeneration,' because it only occurs when the nerve-fibres are degenerated, and irresponsive to all kinds of electric stimulus.

Electric sensibility may be diminished or increased. In general, diminution attends ordinary anæsthesia, and increase accompanies hyperæsthesia. But variations of muscular and cutaneous sensibility are not always in relation with one another. Muscular sensibility is usually impaired when electric contractility is diminished, and augmented when the latter is excessive. Muscular sensibility is increased in cases of muscular rheumatism, and often diminished in hysterical paralysis even when the muscles contract strongly under the electric stimulus.

The condition of things in hysteria presents much variety. But in hysterical paralysis, especially when the muscles have wasted, there is often considerable, but equal, loss of both faradic and galvanic irritability. This is frequently associated with diminution of cutaneous electric sensibility.

*Therapeutical uses of electricity.*—For a full consideration of this important subject we must refer the reader to special treatises.

Meanwhile, however, we may direct attention to a few points in regard to it. Besides its caustic and cauterising effects (for which galvanism is of special use to the surgeon, and as a counter-irritant) electricity possesses stimulant and sedative properties which are of great therapeutic value. Its stimulant properties are specially serviceable in the treatment of paralytic conditions; its sedative and anodyne properties are useful in assuaging various forms of spasms, but are chiefly valuable in the relief or cure of neuralgic affections.

Faradism is in general the more powerful stimulant of muscular and nervous tissues; and it is usually applicable to all paralytic or paretic cases in which any trace of faradic irritability remains, whether it be used for restoring parts which have lost their powers, or for preventing the wasting of disused or disabled muscles. The slowly interrupted galvanic current is also a stimulant, but in most cases a less powerful stimulant than the other.

Fig. 102.—Ziemsse's motor points on the face.

It possesses, however, in addition to the power of exciting muscular contractions, a special influence over the nutrition of the parts to which it is applied. It is better adapted than faradism for the treatment of muscles which have lost their faradic contractility, and it is often employed by preference in the treatment of those which in addition to being paralysed are wasted. Faradism and galvanism are alike useless in paralysed muscles which retain, or have reacquired, their normal electrical reaction.

For sedative purposes faradism is sometimes employed. But it only diminishes spasm or contractility by causing fatigue, and therefore, generally, is not best suited for this purpose. The most valuable sedative for muscular spasm is the continuous galvanic current. This is the only form of galvanism that should be used in the treatment of pain. It is usually advisable to include the painful region between the rheophores in this case, and in neuralgia to apply the one pole over the spinal column above the

FIG. 103.—Ziemssen's motor points on the trunk.

point of origin of the affected nerve, and the other in turn to the several painful spots.

In the habitual use of faradism or galvanism for the above purposes, it is important, in the first place, to employ no greater strength of current than is absolutely necessary to effect the intended result—if to cause muscular contraction, the weakest current capable of causing contraction; if to relieve pain or spasm, only such a current as produces a slight degree of tingling; in the second place, that each sitting should not, as a rule, be continued beyond five, ten, or at most fifteen minutes; and in the third place, that, during this period, every affected muscle or painful point should be brought successively under treatment, and that, in the case of the galvanic current, the negative pole should never be kept for any length of time on one spot.

## II. INFLAMMATION OF THE CEREBRAL AND SPINAL DURA MATER. PACHYMEINGITIS

*Causation.*—Inflammation of the dura mater is either traumatic, or the consequence of the extension of disease from parts external to it, or it is of idiopathic origin. With traumatic inflammation the physician has little to do. Inflammation from extension may be secondary to erysipelas or other such affections of the surface of the head, but is mostly traceable to caries of the petrous or mastoid portion of the temporal bone, or to similar disease of the frontal plate of the ethmoid or adjoining parts of the sphenoid or orbital parietes, or to syphilitic or other like affections of the bones of the skull, or to caries of the vertebræ or sacral bed-sores.

*Morbid anatomy.* 1. *Cerebral dura mater.*—When inflammation extends from the bones of the skull to the dura mater, this membrane becomes thickened and softened, and its connection with the subjacent bone more or less loosened. Not unfrequently a false membrane forms upon its free aspect, and may cause it to adhere to the corresponding surface of the brain; or suppuration takes place, which may either be limited by adhesions, or become widely diffused in the cavity of the arachnoid. Further, inflammatory overgrowth or actual suppuration often takes place between the skull and the dura mater, and in the latter case the dura mater is apt to get perforated, and the pus to be discharged into the cavity of the arachnoid. When inflammation occurs in the neighbourhood of the sinuses, these are liable to involvement and to become the seat of thrombosis or suppuration, or the source of pyæmia. This event is especially common when the meningitis is due to disease of the temporal bone, in which case the lateral, petrosal, and cavernous sinuses may one or all of them suffer.

2. *Theca vertebralis.*—The inflammatory products which are developed during the progress of vertebral caries tend sooner or later to accumulate in the neighbouring part of the spinal canal, between the bones and dura mater. In the majority of cases, according to M. Michaud, this accumulation takes place in the first instance between the back of the bodies of the vertebræ and the vertebral ligament, which gradually undergoes erosion and perforation. The theca vertebralis then becomes involved in the inflammatory process, the outer surface of its anterior portion undergoing proliferation, and possibly forming a kind of caseous button, which, when the cord becomes compressed in this disease, constitutes for the most part the agent of compression. Inflammation of the dura mater, secondary to vertebral disease, may of course occur in any part of its length. In patients who are suffering from extensive bed-sores of the sacral region, it frequently happens that the sacral and coccygeal bones become exposed and eroded. In some of these cases the sacro-coccygeal ligament gets destroyed, and hence the inflammatory process extends into the vertebral canal, or, in consequence of perforation of the theca vertebralis, into the cavity of the arachnoid. Occasionally, consecutively either to vertebral disease, or to

the condition last mentioned, or from some idiopathic cause, the theca vertebralis becomes inflamed throughout, or in great part of its extent, and suppuration takes place on either side of it. The pus which forms externally first accumulates in the spinal canal, and then (if the case be of sufficiently long duration) escapes with the nerves through the intervertebral foramina, and follows their primary ramifications, forming, it may be, a longitudinal series of abscesses behind, on either side of the vertebral spines, and a similar series in front, on either side of the bodies of the vertebræ, of which those in the abdomen possibly constitute multilocular psoas abscesses. The pus which is effused from its inner aspect distends the cavity of the spinal arachnoid, and may spread thence to the base of the brain.

Whenever the pus which is diffused throughout the arachnoidean cavity is derived from gangrenous sources, or from areas of disease communicating with the external atmosphere, it is fetid, greenish in hue, and dirty-looking, and on post-mortem examination the surface of the brain or cord in relation with it is generally found stained to a greater or less depth by imbibition. This peculiarity is most frequently observed in meningitis due to perforation of the theca vertebralis by bed-sores, and in that which takes place consecutively to chronic ear-disease, and is occasionally met with in other varieties of caries of the skull or vertebræ.

3. *Pachymeningitis* is the name given to a peculiar form of chronic inflammation of the dura mater. This may be the consequence, as are the varieties of meningitis just discussed, of injury or of subjacent disease. But it is more commonly of spontaneous origin. *In the head* it commences, for the most part, in the area of distribution of the middle meningeal artery, with the formation, over a greater or less extent of surface, of a delicate adherent film, which consists partly of embryonic corpuscles, but mainly of large, irregular, thin-walled capillaries. Other similar films become developed in slow succession one upon the other over the diseased area until the adventitious formation attains considerable thickness; the deeper-seated laminæ meanwhile becoming denser, more fibrous, and less vascular. Owing to the large size and extreme delicacy of the newly-formed blood-vessels, rupture, with extravasation of blood, is of frequent occurrence. For the most part the hemorrhages are minute and numerous, and result in the precipitation of crystalline and other forms of blood-pigment; not unfrequently, however, they are abundant, and form large accumulations between the laminæ, giving, it may be, to the whole growth the aspect of a mere clot. *Pachymeningitis of the theca vertebralis* usually takes place in the neighbourhood of the cervical enlargement of the cord. The dura mater becomes greatly thickened by the formation of a series of concentric fibroid laminæ, successively developed upon its inner aspect. All of them, even the most recent, are dense and tough, and little vascular or inclined to bleed, and thus differ from those occurring in the cerebral dura mater. In the progress of the disease the pia mater is apt to become involved, and sooner or later the cord is compressed, and the nerves in their passage to the intervertebral foramina are also implicated.

*Symptoms and progress.*—The symptoms which attend inflammation of the dura mater are necessarily vague, unless the inflammation be suppurative or have extended to the pia mater, blood-vessels, or subjacent nervous matter, or involve the compression of the nervous centres, or of nerves. They are especially vague, if not trivial and misleading, in the earlier stages of the chronic forms of the disease. If suppuration take place, febrile disturbance with rigors is likely to ensue; and, as has often been observed, the fever is then apt to assume an irregularly remittent or even intermittent type, and thus the patient's illness may for a time have no little resemblance to an attack of ague. If the disease go on to the effusion of inflammatory products into the cavity of the arachnoid, or to the involvement of the pia mater or substance of the brain or cord, or of nerves, special symptoms referrible to these several parts will of course be developed. We proceed to consider in detail the symptoms of the different varieties of inflammation of the dura mater, the morbid anatomy of which we have already passed in review.

1. *Acute inflammation of the cerebral dura mater*, as met with in medical practice, is almost always due to chronic disease of the ear. Recent otitis, however intense, is rarely followed by it. The patient, who may be of any age between early childhood and advanced senility, has suffered probably for years, perhaps nearly all his lifetime, from deafness, attended with more or less constant, more or less copious, and more or less offensive aural discharge, and occasional attacks of ear-ache.

The supervention of meningeal mischief is induced sometimes by exposure to cold, sometimes by a blow on the affected side of the head or on the jaw, and not unfrequently seems to occur spontaneously. Very often it is preceded by or attended with sudden diminution or cessation of discharge. The patient is usually attacked with intense pain in the affected ear or its neighbourhood, or possibly with severe headache referrible to some other part of the head. This, which is generally more or less constant, is attended with exacerbations which are often so violent that he writhes and groans or grinds his teeth and even shrieks out. Not unfrequently it continues as long as the patient retains consciousness; but it often remits or disappears, and in some cases is wholly wanting from first to last. It is probably for the most part referrible to the disease of the ear rather than to that of the internal parts. Sometimes a paroxysm of convulsions is the earliest specific indication of meningeal mischief; sometimes vomiting; sometimes an attack of vertigo, incoherence, or rambling; sometimes a rigor. The disease is subject to remarkable variations, both as to duration and as to the phenomena which attend it. Assuming it to prove fatal, the patient may die in the course of two or three days; more commonly he survives for two or three weeks; but his life may be prolonged for several months. In the last case especially, intervals of apparent restoration to health probably occur; thus, in some instances, the patient has a convulsive attack, attended perhaps with vomiting, from which he recovers, and a second attack, which proves the precursor of fatal symptoms, does not take place for some days or weeks;

in some instances he has strabismus and double vision, which may disappear from time to time, but are finally associated with graver phenomena; in some he suffers from a combination of symptoms threatening speedy dissolution, from which, nevertheless, he emerges, but only to become sooner or later the victim of a relapse.

The symptoms of the established disease comprise, in addition to headache localised in the ear or occupying the forehead, vertex, occiput, or other parts of the head, vertigo, intolerance of light and sound, hyperæsthesia, neuralgic pains in the head, neck, and limbs, nausea and vomiting, sleeplessness, restlessness, and irritability, muttering, busy or maniacal delirium, convulsions, local or general, occurring at rare intervals or following one another in rapid succession, paralysis limited to certain of the cerebral nerves or hemiplegic, drowsiness and coma, together with febrile symptoms. But these are not all necessarily present in the same case. Occasionally the patient, after suffering from severe pain in the ear, and possibly indefinite symptoms of brain-affection, falls into a state of collapse; sometimes he suffers mainly from convulsions, which are attended or succeeded by paralysis and coma; sometimes paralytic symptoms are the main feature of his malady—he becomes hemiplegic or has paralysis of some of the muscles of one of the eyeballs or of the portio dura, or he has difficulty in speech or deglutition, or he loses the sight of one or both eyes; sometimes he suffers mainly from mental derangement; sometimes he has frequent and severe rigors, coming on at intervals, with other febrile symptoms, such as coated tongue, heat and dryness of skin alternating with perspirations, rapid pulse and the like. In other cases the skin is cool, the pulse of normal rate, and there is total absence of febrile reaction.

The differences of symptoms which different cases present are no doubt in great measure attributable to differences in respect of the depth or superficial extent to which the inflammatory process extends within the skull. If the inflammation be limited to the dura mater, even should this become sloughy and pus accumulate between it and the bone, the symptoms are in a large number of cases undistinguishable from those due to otitis alone, and may be uncomplicated with fever. Again, if the inflammation reach the free surface of the dura mater, and especially if pus escape into the arachnoidean cavity, it is natural that aggravated brain-symptoms should be suddenly excited, that fever should be developed, that some of the nerves at the base of the brain should become implicated, and that some of the symptoms of cerebro-spinal meningitis, such as retraction of the head and pain on moving it, should be experienced. Further, if abscesses form in the contiguous brain-substance, symptoms due to their presence are likely to arise. When inflammation of the dura mater involves thrombosis of the sinuses which are contained in its laminae, escape of blood from contiguous parts of the brain may be impeded. The most interesting phenomena, however, are those which are referrible to the veins of the face and neck which are in continuity with the obstructed sinuses. Thus it sometimes happens that the veins in the eyelids and

conjunctiva of the affected side get preternaturally distended with blood ; or that inflammation of the internal jugular in the neck occurs, with formation of deep-seated abscesses in that situation. Optic neuritis, too, is often present. Lastly pyæmia is not unfrequent ; and, although rigors may be caused by local suppuration or by effusion of pus into the arachnoid, they are far oftener an indication that the affection of the ear has become complicated with inflammation of the sinuses and purulent infection.

It may be added : that the pulse is liable to great variations, that it may be accelerated, or of normal rate throughout, that it is sometimes preternaturally slow, and generally, when death approaches, becomes very rapid and feeble ; that the skin is sometimes hot and dry, but often perspires profusely, especially towards the close ; and that generally during the course of the disease Trousseau's ' tache cérébrale ' can be elicited ; that the tongue differs in its character, is often natural, but tends to become coated, and with the approach of death dry and brown ; that the evacuation of urine and feces is often performed unconsciously ; and that in the course of the disease symptoms are sometimes relieved by the sudden discharge of pus from the ear or even from the nose.

Death is usually due to collapse or to coma ; it may, however, be caused by asphyxia, or be traceable to the effects of pyæmia. Occasionally the cerebral symptoms, developed during the progress of otorrhœa, and death, are due not to the ear-affection, but to tubercular meningitis arising in connection with it.

2. *Pachymeningitis of the cerebral dura mater.*—The symptoms which attend this disease are exceedingly vague, and none the less so that it usually affects aged persons in a state of imbecility or dementia. It has also been observed, according to M. Lancereaux, in cases of chronic alcoholism and chronic pulmonary phthisis. The symptoms include pain in the head, vertigo, failure of the mental powers, and gradually increasing hemiplegia, with occasional epileptiform or apoplectic attacks, in one of which the patient probably dies.

3. *Acute general inflammation of the theca vertebralis*, such as results from its perforation by a bed-sore or the extension of inflammation occasionally following fracture or caries of the spine, is sometimes attended with marked symptoms, but is often extremely obscure in its indications. The symptoms which may be looked for are : pain in the course of the spine, sometimes of an exceedingly intense character, and for the most part liable to aggravation by any movement, voluntary or involuntary, of the limbs, trunk, or head and neck ; rigidity of the muscles, with perhaps twitching ; and at the same time more or less loss of motor power, and probably of sensation, and of control over the bladder and rectum. To these, cerebral symptoms are apt to be superadded, more especially delirium, convulsions, and coma. Further, there may be tenderness in the course of the spine, due partly to the disease within it, partly, perchance, to the extension of suppuration into the muscles of the back. In cases of sufficiently long duration and sufficient intensity, it is possible that

psoas abscesses may be discernible by palpation in the neighbourhood of Poupart's ligament. When the inflammation is due to the extension of bed-sores which have become developed during the progress of paralytic or other diseases, attended with impairment of the mental faculties, its presence is almost certain to be overlooked. Some degree of febrile disturbance will probably always be present.

4. *Caries of the vertebræ*, even when it is attended with considerable displacement, does not of itself usually cause paralysis. The paraplegia, indeed, which so commonly attends the disease, is almost invariably due to extension of the inflammatory process to the membranes of the cord and to the cord itself, and to pressure caused by the accumulation of inflammatory products.

Among the early symptoms of involvement of the nervous contents of the spinal canal (in addition to local pain and tenderness, and possibly angular curvature, indicative of the bone affection) must especially be noticed burning pains in the course of some of the nerves springing from the implicated portion of the cord. These pains, according to the situation of the disease, may involve the nerves of one or both shoulders or arms, or one or both great sciatic nerves, or certain of the intercostal nerves, or of those of the abdominal walls. They are liable to come and go, and when continuous are often attended with exacerbations; moreover, there may be hyperæsthesia in the area of their distribution. The sense of constriction, often likened to the feeling as of a cord drawn tightly round the chest or abdomen, which is so commonly complained of by paraplegic patients, belongs to the same category. These morbid sensory phenomena are due to involvement of the sensory roots of spinal nerves, which generally occurs before the cord itself suffers; and it not uncommonly happens at this period that erythematous or vesicular eruptions or pemphigus becomes developed in the area of distribution of the affected nerves, or even more extensively. It need scarcely be said that motor branches may also be involved, and that limited motor paralysis and atrophy of muscles may ensue. If the disease occupy some considerable length of the spinal canal, or a part in which nerves only are present, the several phenomena due to implication of nerves alone may become pretty widely distributed. Thus, if (as not unfrequently happens) the disease occupy the situation of the cervical enlargement, there may be hyperæsthesia, burning or pricking pains, and cutaneous eruptions, involving one or both arms, with flaccidity and wasting of the muscles, and rapid loss of faradic contractility, followed after a time by anæsthesia and complete motor paralysis of the same parts, but without any involvement whatever of the lower part of the body; if it be in the situation of the cauda equina, one or both lower extremities will probably suffer in the same manner as the arms in the former instance. In either case there will be partial or total absence of reflex movements in the affected limbs.

After a time, which varies in different cases, symptoms due to involvement of the cord come on. These consist, in the first instance, in

numbness, tingling, or formication in the affected limbs, together with impairment of muscular power. The latter generally increases more or less rapidly until complete motor paralysis is established. The impairment of sensation, on the other hand, for the most part remains stationary, or undergoes amendment, or varies from time to time. But it may of course go on to absolute anæsthesia. As a rule, the muscles below the seat of disease, even if there be total abolition of sensation and motion, retain their natural tonicity and plumpness; their faradic contractility remains normal or increases; and reflex movements may be much more readily induced in them than in health. Such movements, indeed, are often provoked by the contact of the bed-clothes, or the passage of evacuations. Occasionally, however, there is marked diminution or even abolition both of reflex action and of faradic contractility. If the involvement of the cord persist, the ordinary ascending and descending lesions take place, the former along the posterior median columns, the latter along the lateral columns. The progress of the latter complication is attended with: aggravation of reflex phenomena, and especially the occasional occurrence of tremulous movements, lasting for a few seconds or even for many minutes at a time in the affected limbs; the supervention from time to time of clonic or tonic spasms; and gradually increasing rigidity of the muscles, which in the first instance goes along with extension of the limbs, but at a later period with flexion.

The symptoms which attend the form of paraplegia under consideration present considerable differences, in dependence partly upon the situation of the spinal caries, partly upon the degree in which the cord is involved. Thus, when the disease is in the dorsal or lumbar region, one lower extremity only may be affected, or both may suffer in different degrees, or there may be cross paralysis, with loss of motion on one side and impairment of sensation on the other; when the disease is in the neck the arms are commonly affected prior to the legs, and they may be involved unequally; and, even when legs and arms are all implicated, the paralytic phenomena in each may present differences both in degree and in kind. Thus, also, while the rectum and bladder are often little if at all compromised when the lumbar or lower dorsal region is affected, want of control over these viscera is usual when the disease involves the upper dorsal or cervical region; and, indeed, in the latter case this want of control occasionally precedes all other paralytic symptoms. Further, when the cervical spine is the seat of disease, various phenomena, of more or less interest or importance, are apt to be superadded to the simple paraplegic symptoms, among which may be enumerated cough, difficulty of breathing and of speech; difficulty of deglutition, hiccough, vomiting and gastralgia; epileptic attacks; permanent slowness of the pulse, with frequent tendency to faint; affection of the pupils of one or both eyes—in the first instance dilatation, at a later period, and more commonly, contraction; and especially in cases in which pupil-changes are present unilateral or bilateral sweating.

The prognosis of paraplegia dependent on caries of the vertebræ is, so far as the paralysis is concerned, not unfavourable; that is to say, presuming that the patient is not carried off by the effects of long-continued suppuration or of degenerative changes in internal organs, by rapid extension of inflammation throughout the cord, or by pulmonary phthisis or other complications, there is always good reason for anticipating, in a case that comes early under observation, a more or less complete restoration of motion and of sensation. Cures have often been effected in patients who had been completely paralysed for one or two years, or even longer. And, indeed, it has been shown by anatomical evidence that substantial recovery has occurred in cases in which the cord has been permanently reduced in diameter by pressure, and impaired in its texture by interstitial growth, or the development of secondary ascending and descending lesions. It is obvious that those patients who have caries of the cervical vertebræ incur many more, and more serious, risks than those who suffer from dorsal caries; and, when the atlanto-axial articulation is the seat of disease, sudden death from rupture of the ligament and consequent sudden compression of the upper extremity of the cord is to be dreaded. Apart from the causes of death which have already been enumerated, paraplegic patients are apt to sink from the effects of bed-sores or from the consequences of vesical and renal inflammation.

5. The symptoms referrible to *cervical pachymeningitis* are not unlike those which sometimes attend cervical caries. The affection presents two stages. The first or painful stage, which lasts two or three months, is characterised by extremely acute pains in the back of the neck, shooting thence to the head and along the upper extremities. These are for the most part constant, but liable to exacerbations. The pains are attended with rigidity of the muscles, most strikingly manifested in those of the neck, which is kept fixed in a position identical with that assumed in cervical caries. At the same time the patient complains of formication, a sense of weight in the limbs, and loss of muscular power. Bullous eruptions, too, are not unfrequent. The above phenomena are due to compression and irritation of the nerves. In the second stage the nerves become disorganised, and the spinal cord suffers. The pains in the arms now cease, but the muscles become paralysed and undergo atrophy. It is remarkable, however, that the muscles of the forearm supplied by the musculo-spiral and especially by the median nerve are mainly implicated. Consequently the extensors predominate over the flexors, and the hand assumes the form of a claw. This peculiarity, though not special to cervical pachymeningitis, is special to it among diseases of spinal origin causing muscular atrophy. Subsequently contractions of the affected limbs take place, and areas of total anæsthesia appear in them and in the upper part of the trunk. Later the lower extremities become paralysed and contracted, but they do not undergo atrophy.

*Treatment.*—The treatment of inflammatory affections of the dura mater and of the lesions so commonly associated with them is on the whole unsatisfactory. We have, as a rule, little or no direct influence over the

progress of acute internal inflammation ; and chronic inflammatory processes occurring in deep-seated parts are equally seldom amenable to direct treatment unless they be due to certain specific diseases.

1. If we have reason to suspect the presence of circumscribed suppuration between the dura mater and bone, or in the parts immediately internal to the dura mater, the question of aiding the escape of pus will naturally present itself. If, therefore, the patient have a scalp wound, or be suffering from fracture, necrosis, or syphilis of any part of the skull, it will probably be deemed advisable to apply the trephine. If the source of mischief be the ear, that organ must be carefully examined ; if there be evidence of accumulation of matter in the tympanum, the membrane, assuming it to be whole, should be punctured or incised ; if it be already perforated and the discharge offensive, the cavity should be washed out carefully with antiseptic solutions ; if there be evidence of suppuration in the soft parts about the mastoid process, or behind the angle of the jaw, a free incision should be made ; and, further, if we have reason to suspect the presence of pus in the mastoid cells, these should be laid open by the trephine. But the inflammation is not always suppurative ; and the application of leeches over the mastoid process or in its vicinity often affords relief, especially in the early stage of the disease, and may possibly tend to arrest its progress. Hot fomentations and poultices to the part are not unfrequently grateful to the patient, and they may be rendered more so by the addition to them of opium, belladonna, aconite, or other preparations having sedative properties. Evaporating lotions or ice to the head also are generally serviceable. As regards internal treatment, it is well in the first place to maintain free action of the bowels, and to restrain as far as possible sickness or other distressing symptoms. Iodide of potassium may also be administered. There is a general feeling against the employment of narcotics in these cases ; we must declare, however, that we have often seen much relief to agony and restlessness afforded by the exhibition of largish doses of laudanum or morphia, and never any injurious consequences. If the affection take a chronic or subacute course, it may be well to administer iron, preferably perhaps the syrup of the iodide, or quinine, or cod-liver oil, and to have recourse to counter-irritants. The patient should of course be kept extremely quiet, and be carefully watched, and his diet and secretions should be regulated.

2. The treatment of cerebral pachymeningitis is that of old paralysis and other chronic organic lesions of the brain.

3. For the local treatment of general acute inflammation of the theca vertebralis, leeching, fomentations, the application of ice, and counter-irritation may be enumerated ; but more important perhaps than any of these is the maintenance of the patient at perfect rest, either on his back or in a position midway between the back and side. Iodide of potassium may be administered here as in the former case ; but tonics, stimulants, and opium are more likely to be of service.

4. Paraplegia from vertebral caries must be treated by absolute rest in the supine position, on a bed specially adapted to the case, and with

suitable arrangements for the discharge of the patient's evacuations without the need of movement. And this rest must be maintained for a considerable period; indeed, as has already been remarked, a period of one or two years or more may elapse before even a trace of returning muscular power can be observed. In addition, counter-irritation to the neighbourhood of the part affected appears often to be of essential service; the best forms are issues, which should be kept open, or the actual or galvanic cautery, applied on one or both sides of the spine. The general health of the patient should be maintained by good diet, stimulants, and tonics; and great care should be taken to prevent the supervention of bed-sores and of inflammation of the bladder. If the muscles show signs of wasting from disuse, the employment of faradism or of the direct current may be had recourse to—a mode of treatment which may also be beneficial in promoting recovery when recovery is in progress.

5. Spinal pachymeningitis should be treated on the same principles as paraplegia from caries.

### III. CEREBRAL AND SPINAL MENINGITIS. TUBERCULAR MENINGITIS (*Acute Hydrocephalus*)

*Causation.*—The causes of meningitis are various. In some cases it depends on the spread of inflammation from adjacent parts—from the brain or cord, from the dura mater or the bones, and more especially from the internal and middle ear; indeed the latter affections rarely produce cerebral symptoms without involving the pia mater to some extent. In quite young children the association of diffuse meningitis with suppurative inflammation of the inner parts of both ears is not uncommon. In some cases it is secondary to the presence of adventitious products, such as miliary tubercles, tumours, and apoplectic clots. It may be the result of injury or of direct exposure to the rays of the sun. It is sometimes of idiopathic origin, sometimes due to pyæmia or to ulcerative endocarditis, and sometimes (as apparently in epidemic cerebro-spinal meningitis) produced by contagion. Tubercular meningitis, which is in fact by far the most common form of cerebral meningitis, may occur at any date between early infancy and old age. It is probably most frequent before puberty; but is common up to thirty. It is noteworthy that tubercular meningitis is sometimes a complication of otitis interna.

*Morbid anatomy.*—1. *Cerebral meningitis* is characterised essentially by dilatation and hyperæmia of the vessels of the pia mater, and the effusion of coagulable lymph and inflammatory corpuscles into the meshes of the subarachnoid tissue. The first naked-eye evidence of inflammation is the presence of congestion, which often assumes a patchy character; to this, opaline effusion into the subarachnoid tissue succeeds; and presently the corpuscular and other solid products accumulate, at first more especially on either side of the larger superficial veins, whence they gradually creep over the surface of the convolutions and into the depths

of the sulci. In some cases the yellowish or greenish opaque exudation here referred to occupies mainly the prismatic intervals situated between contiguous convolutions and the visceral layer of the arachnoid; in some, where it has spread over the convexity of the convolutions, the surface of the brain becomes mapped out into a series of rounded or irregular congested areas, separated from one another by an irregular network of inflammatory exudation; in some cases, again, the accumulation is so considerable that the surface is uniformly covered with it and the sulci are widely distended. This exudation, which is often solid like an ordinary false membrane, occasionally becomes distinctly purulent. The inflammatory process, which is limited mainly to the substance of the pia mater and to the subarachnoid tissue, nevertheless affects to a greater or less extent the neighbouring arachnoid on the one hand, and the cortex of the brain on the other. The accumulation in the subarachnoid tissue tends to expel the fluid from the arachnoid cavity; and in cases of extensive inflammation this fluid wholly disappears, and the surface of the brain becomes sticky and almost dry. The actual appearance in such cases of inflammatory products on the free surface of the arachnoid or within its cavity is rare. The intimate connection subsisting between the vessels of the pia mater and those of the cerebral cortex renders it almost essential that these should share in any process which involves the former. And to a certain extent they do thus share; they become dilated and congested, and more or less inflammatory change takes place in the brain-tissue enclosed within their meshes.

Inflammation may involve any part of the pia mater, and may spread to any extent over it; indeed meningitis, like erysipelas and many other forms of inflammation, has a marked tendency to diffuse itself superficially. Sometimes, however, it occupies mainly the convexity of the hemispheres; sometimes mainly the base of the brain; sometimes mainly the surface of the cerebellum, pons Varolii, and medulla oblongata. In the last case the inflammation usually spreads along the spinal cord. It frequently also involves the velum interpositum and choroid plexuses; and, probably on this account, the lateral ventricles usually get distended with fluid. Further the ependyma of the ventricles is often rough from the presence of minute granulations, and the white matter around the ventricles is often reduced to a pulp.

2. *Meningitis due to tuberculosis* nearly always begins at the base of the brain, is often limited to the base, and is generally most intense there. It differs anatomically from simple meningitis in the presence of grey miliary tubercles, varying from the size of a pin's head downwards. These may be so few in number or so minute as almost to defy detection; they may be so abundant as to form large granular clusters, or irregular, cheesy patches of considerable extent and thickness. They commence in connection with the arterioles, whose channels they soon obliterate, and hence congregate especially along the vessels. They are found mainly in the neighbourhood of the circle of Willis, extending thence along the fissures of Sylvius to the lateral aspects of the hemispheres, around the

crura cerebri into the great transverse fissure of the brain, and thence to the velum interpositum and choroid plexuses, and also over the pons Varolii. But they are not limited to these situations. They seldom involve the visceral arachnoid, or appear on its free surface; they tend, however, to become developed in connection with the small vessels of the cortex, so that if the pia mater be torn away a greater or smaller number of these vessels with tubercles in their walls are often also torn away, together with portions of the cortical matter itself. Not unfrequently, indeed, masses of tubercles at the bottom of the sulci appear to be imbedded in the substance of the brain. Minute superficial hemorrhages are common in this condition. When tubercles are few and small, they may sometimes be recognised by the finger as minute hard granules, or be seen on holding up detached laminae of pia mater to the light; or they may need the microscope for their discovery. Dr. Angell Money finds that in about one-third of the fatal cases of tubercular meningitis there are miliary tubercles in the choroid coat of one or both eyes. He finds also that choroidal tubercles are sometimes present, associated with tubercles of other parts, even when there is no meningeal tubercle whatever.

3. *Spinal meningitis* corresponds essentially in all its characters to the description which has been given above; moreover, the presence of tubercles here is not unfrequent. They occur especially over the cervical and lumbar enlargements and on the inner surface of the dura mater.

*Symptoms and progress.*—1. *Cerebral meningitis.* It is impossible to make any practical clinical distinction between simple and tubercular meningitis; we shall include them, therefore, in a common description. Meningitis, especially when it occurs in children, is said generally to be preceded by premonitory symptoms which may vary in their duration from a week or two to some months. They are probably only observed in cases of tubercular meningitis, and are referrible in some degree to the fact that tubercles are already in process of development in the meninges, and in some degree perhaps to the presence of these bodies in other organs, such as the lungs, bowels, and serous membranes. The premonitory symptoms are variously described, and the majority of them have no distinctive characters. The child perhaps becomes emaciated, weak, and pallid, loses appetite, suffers from constipation, is irritable, fretful, sad, indisposed to play, drowsy in the daytime, and wakeful at night, his sleep being attended with startings and grinding of the teeth, and disturbed by dreams, from which he wakes up frightened and screaming. He may suffer also from febrile disturbance. Amongst other occasional premonitory symptoms may be mentioned some of those which belong to the earlier stages of the established disease, especially vertigo, headache, squinting, sickness, and slowness with irregularity of pulse.

The symptoms of invasion, whether preceded by prodromata or coming on without them, are exceedingly various. The patient complains: in some cases of pain across the temples, through the eyes, or elsewhere in the head, which is more or less persistent, but liable to paroxysmal exacerbations; in some of vomiting, coming on frequently, without apparent

cause and not necessarily attended with marked impairment of appetite ; in some of fever of irregularly remittent type, attended, it may be, with rigors ; in some of double vision. Sometimes the first indications of disease are furnished by dulness, strangeness, or wildness of manner, by impairment of memory or defect of speech, or by the collective symptoms which characterise the early stage of delirium tremens. Sometimes the attack is ushered in by an epileptic seizure.

The progress of the disease is usually divided into three stages, which in typical cases are often fairly well marked. The first stage, which includes the invasion, is generally characterised by fever, elevation of temperature, increased rate of pulse, and the phenomena of nervous irritation ; the second stage is usually attended with diminution or cessation of fever, slowness of pulse, or the phenomena of commencing paralysis ; the third stage, or that of collapse, is the stage usually of convulsions and coma, during which also febrile symptoms not unfrequently again manifest themselves and the pulse becomes extremely rapid.

The first stage is ushered in for the most part with various combinations of the symptoms above enumerated, and is generally attended with elevation of temperature—febrile exacerbations, often associated with rigors, coming on irregularly and sometimes several times a day ; acceleration alternating with slowness of pulse ; headache, which is often so severe that the patient screams out with it, or supports his head with his hands, and which is not unfrequently associated with tenderness of the scalp and neuralgic pains in the back of the neck, extending, it may be, to the limbs ; nausea and vomiting ; constipation ; disturbed sleep or sleeplessness ; sadness and taciturnity, or querulousness, or tendency to delirium. To these symptoms are not unfrequently added hyperæsthesia, tremulousness and muscular debility, intolerance of light and sound, hemianopia, illusive appearances, double vision or squinting from spasm of the muscles of the eyeballs, and contracted pupils. In this stage young children are generally fretful, peevish, agitated at the approach of strangers, and resentful at the attentions of the nurse or mother, and not unfrequently even now utter the characteristic hydrocephalic cry.

In the second stage the patient becomes comparatively quiet, and passes into a drowsy condition ; his temperature for the most part falls somewhat, and, though generally still a degree or two above the normal, may sink to the normal, or even below it ; and his pulse becomes slower than natural, and at the same time more or less irregular. The transition from unrest to rest, and the subsidence of fever, give a delusive aspect of convalescence. In this stage the cephalalgia, the exaltation of the senses of sight, hearing, and touch, the nausea and sickness, and the irritability of temper, or sadness, or moroseness, all subside, and the patient becomes apathetic. He perhaps sleeps continuously, and is roused with difficulty to put out his tongue or take nourishment ; he probably does not refuse food, but he does not ask for it ; nor does he trouble himself to restrain his evacuations. His breathing, like his pulse, is irregular, and characterised by a series of rapid respirations, followed by long intervals of

complete apnœa. It is during this period that certain other phenomena are peculiarly apt to be present—to come on for the first time, or to undergo aggravation. The hydrocephalic cry, in children especially, now becomes a marked feature of the case; it is uttered at frequent but irregular intervals. The following is Trousseau's description of it:—'He from time to time opens his eyes wide, which shine as they do in persons who are drunk. His face, which is usually extremely pale, flushes for a minute or two; then he closes his eyes again, and resumes his former aspect. Generally, as he thus opens his eyes, and as his face colours up, the child utters a sharp plaintive cry, which is perfectly characteristic.' 'Most frequently it is single and loud like the cry of a person frightened by some sudden danger.' The face, which is generally pallid, is liable to sudden temporary flushes, and the tache cérébrale is easily produced. Retraction of the abdomen is almost always present. During this stage the patient is apt to roll his head from side to side, to move his hands and arms restlessly, to wave them or throw them about, to pluck at the bed-clothes, or to pick his nose, lips, or ears, and to perform various other movements; he may suffer from quiet delirium, or present partial convulsive movements of his face or limbs; his pupils may get dilated or unequal, and irresponsive to light; sight may fail; and paralysis may come on, especially ptosis, paralytic strabismus, paralysis of the portio dura or hypoglossal, or hemiplegia.

The third stage is characterised by the supervention of convulsions and coma, or of coma alone. The patient, who could hitherto be roused with more or less ease, now scarcely responds to any external influence. He is anæsthetic, deaf, blind, the pupils are dilated, probably unequal, and react slowly or not at all to light. Sometimes inflammation or ulceration of the cornea takes place. Paralysis has become more pronounced either in certain muscles or groups of muscles, or on one side of the body. He still, however, rolls his head about; still has subsultus or tremors, or picks at the bed-clothes; still utters the distressing cry peculiar to the disease. The respirations get more frequent and irregular. The pulse may still remain below the normal rate, but more usually becomes exceedingly rapid and feeble. The temperature for the most part rises, especially in the internal organs; that is to say, the limbs get cold and dusky, while the trunk and viscera are burning hot. But the temperature during this stage is liable to great variety: in one case it rises rapidly as death approaches; in another it remains elevated two, three, or four degrees above the natural standard; while in yet another it falls ten or fifteen degrees, or more, below it. The cheeks are alternately pale and flushed, and the surface bathed in sweat. The tongue, which during the earlier stages may have been natural, or may have presented more or less whitish fur upon its surface, in the third stage generally becomes thickly coated, dry, and brown, and the teeth get covered with sordes. Convulsions, as a rule, are now frequent, sometimes incessant, sometimes slight, sometimes violent, sometimes limited to the face or to the hands, sometimes unilateral, sometimes general. They are apt to increase in severity

as the fatal end approaches ; and the patient, who always dies comatose and sometimes collapsed, is not unfrequently carried off in a convulsion.

In addition to the delusive appearance of amendment which characterises the beginning of the second stage, it is not uncommon, towards the close of the second or beginning of the third stage, for the patient to wake up, as it were, from his semi-coma or coma, to recognise his friends and to take an interest in what is going on around him. The amendment may last a day or two, and may recur, and is apt not unnaturally to raise the hopes both of the friends and of the medical attendant. Unfortunately, however, these hopes are, almost without exception, doomed to speedy disappointment, and, sooner or later, all the symptoms return, become aggravated, and death ends the scene. It is, nevertheless, a fact not only that temporary recovery may take place, but that patients who present distinct symptoms of meningitis now and then recover permanently. Recovery even from the tubercular variety of the disease is possible.

The duration of cerebral meningitis is very uncertain. It is generally from one to three weeks, and not unfrequently about a fortnight. It may be only three or four days. The different stages also which have been enumerated vary in duration, both actually and relatively, and in all cases the transition from one to another is quite gradual.

It must never be forgotten, however, that although there is a common tendency for the progress of meningitis to divide itself into successive stages, and although these successive stages have a tendency to assume such characters as have been above assigned to them, in a very large proportion of cases the symptoms and progress of the disease diverge widely from the type. No disease, indeed, is more protean in its features than meningitis, probably none simulates so many other disorders. In some cases, as for example when meningitis complicates acute pneumonia, erysipelas, or other inflammatory affections, the only indication of what proves to be extensive meningitis may be the supervention of drowsiness, coma, and collapse during the day or two preceding death. In some cases, indeed, even when the inflammation of the brain is uncomplicated, drowsiness and coma are the only symptoms ever recognised. In many cases the early stage of the disease is mistaken for inebriation or delirium tremens ; and indeed the symptoms of meningitis are not unfrequently, during the greater part of its duration, almost exact counterparts of those of delirium tremens. In other cases the symptoms have a close resemblance to those of enteric fever, and in children to that vague and uncertain malady which is commonly termed ' gastric fever '—especially to those cases of these affections in which the accustomed diarrhoea is replaced by constipation, and the abdomen fails to present its ordinary flatulent distension, while at the same time nervous phenomena, such as headache, sleeplessness, irritability, and delirium prevail. In other cases, again, meningitis presents many of the features of general tuberculosis ; it must be recollected, however, that general tuberculosis is very apt to be attended with involvement of the surface of the brain, and that hence the supervention of meningitis in the course of the general disease should not be overlooked. Sometimes the patient,

from the commencement of his malady up to the occurrence of coma, is in a condition of mild delirium ; occasionally, but much more rarely, he is in a state of maniacal excitement ; sometimes epileptic convulsions predominate ; sometimes he is sensible from first to last. In some instances headache and vomiting never present themselves ; in some the temperature scarcely ever rises above the normal ; in some there is a total absence of affection of the optic discs ; in some distinct paralysis never occurs ; in some paralytic phenomena form the most striking features of the malady. The hydrocephalic cry may never be uttered.

Still, however obscure the case may be, there is almost always something during its progress which reveals to the observant practitioner its fatal character. The cloven foot shows itself.<sup>1</sup> There is vomiting without obvious cause, or fever of a certain character, or retraction of the head, or hyperæsthesia ; or there is some affection of the pupils, or some temporary or permanent paralysis, even though it be limited to the levator palpebræ or one of the ocular muscles ; or there is some convulsive movement, or the characteristic distressful cry, or some peculiar change in the mental condition ; or the respirations are characteristically irregular ; or the muscular debility and tremulousness are out of all proportion to the other symptoms generally exhibited ; or optic neuritis is present, and often even from the earliest period of the patient's illness ; and generally also Trousseau's tache cérébrale, a phenomenon, however, of little importance, can be readily developed. This consists in the speedy appearance and long duration of a comparatively wide blush of redness in the course of a line made by drawing the finger-nail or the point of a pencil along the skin, more especially on the face, abdomen, and inner aspect of the thigh. Since the larger number of cases of meningitis are of tubercular origin, accuracy of diagnosis may often be ensured by careful attention to the history of the patient, and by careful examination of his lungs and other organs in reference to the presence of tubercular disease in them. As we have already pointed out, tubercles of the choroid are by no means uncommon ; but they are seldom recognisable during life.

The great variableness of the phenomena which attend meningitis becomes easy of explanation when we look to the morbid anatomy of the disease, and consider how many parts are liable to suffer, and how unequally they may be involved. We have seen that the morbid process, especially if it be of tubercular origin, is peculiarly apt to invade the cortical substance of the brain. What wonder that mental phenomena and convulsions should ensue, and that these should vary largely in their details in different cases ? We have seen how almost invariably the base of the brain suffers more than other parts, and how the nerves are consequently liable to be involved in the inflammatory process. What wonder that hyperæsthesia and paralysis, variable as to their seat and degree, should be present ? We have seen that the lateral ventricles are apt to get distended with fluid, their parietes softened and compressed. Is it remarkable that, when these changes take place, profound coma is of common occurrence ?

2. *Spinal meningitis*.—The symptoms of acute inflammation of the spinal pia mater differ but little from those which have been ascribed to inflammation of the theca vertebralis, and necessarily have some resemblance to those developed in the course of myelitis. Indeed, many of the symptoms which occur in inflammation of the dura mater are really due to the extension of disease to the pia mater; and many of those of inflammation of the pia mater are essentially referrible to involvement of the subjacent nervous matter.

When any considerable length of pia mater is affected, more or less fever of a remittent character, and possibly attended with rigors, will very likely be present. There will probably also be anorexia, thirst, and abnormal rapidity of pulse. Sometimes, however, the pulse is slow. The patient most likely complains of pain in the course of the spine, not much increased by simple pressure, but greatly aggravated and sometimes amounting to unendurable agony when either muscular movements are performed or the spinal column is bent or twisted. There is generally rigidity of the voluntary muscles—the muscles of the back, and more especially those of the neck, being chiefly affected, and the head consequently retracted; the elbows are apt to stand out from the body, and the forearms and hands to be somewhat flexed; the lower extremities are probably similarly affected; the jaws are often firmly closed, and the muscles of the face contracted so as to give to the expression the well-known risus sardonicus. Further, sudden twitches and spasms of a tetanic character are apt to occur from time to time, not only in the muscles of the back, which becomes consequently a little more arched, but in those of the limbs and head and neck. At the same time the patient complains of pain, not merely in the back, but also in the head, and especially in the extremities, into which it shoots in sudden paroxysms, which are excited whenever he executes any movement, or his muscles are forcibly disturbed by the hands of the attendant. There is not unfrequently also hyperæsthesia.

Partly mingled with these phenomena, but more especially supervening upon them is impairment of voluntary movement and sensation; the patient loses more and more the power over those limbs which correspond to or are below the seat of lesion; and he loses also, in a greater or less degree, control over the rectum and bladder. Indeed incontinence of urine and fæces is apt to take place even when paralysis of the voluntary muscles is very slight, and while at the same time the patient's mental faculties appear to be intact. Tingling, formication, or numbness is not unfrequently present. If the disease involve the higher part of the spinal pia mater and that of the medulla, difficulty of respiration, speech, deglutition, and mastication may be present. Priapism and increased irritability of the excito-motor functions are, though rarely, observed. Vertigo, headache, slight delirium, and other cerebral phenomena generally arise in the course of the malady, especially if the meningitis extend from the spine to the base of the brain.

The main features of the disease appear to be: pain along the spine

and shooting into the extremities, especially aggravated by movement; hyperæsthesia; rigidity with occasional spasmodic contraction of the voluntary muscles; and want of power over the rectum and bladder. Absolute paralysis is rare, and absolute anæsthesia still rarer. Indeed the patient, who has probably been for some days confined to his bed, apparently unable to move, and suffering agony when involuntary or other movements are effected, and exerting no control whatever over his evacuations, will sometimes suddenly, in his restlessness, agony, or delirium, sit up in bed, or even get out of bed and pace the room.

The commencement of the disease, especially if it be secondary to any other serious malady, is often insidious and obscure. And even when it is of purely idiopathic origin, the symptoms may be so slightly pronounced during the first three or four days that the patient refuses to go to bed, and in some cases goes on with his usual avocations. The initial symptoms are not unfrequently pain, usually supposed to be rheumatic, in the course of the spine and of the nerves which are given off from it, increased by movement, febrile disturbance, restlessness, irritability of temper, and sleeplessness.

Spinal meningitis is a very fatal malady, and although doubtless some persons recover from it, the great majority die, succumbing for the most part between the third or fourth day and the third or fourth week. Most deaths, however, occur within the week, and are due either to asphyxia or to asthenia, the latter often being promoted by the rapid supervention of bed-sores and other complications.

*Treatment.*—Cerebral meningitis for the most part defies all medical treatment; still, as recovery certainly takes place occasionally, even when it is of tubercular origin, it behoves us to give some care to the management of all cases of the kind that come under our charge. The patient should be placed in a room sufficiently darkened to be grateful to his irritable eyesight, sufficiently quiet to prevent all auditory disturbance, and at the same time cool and well ventilated. He should be carefully watched by a quiet and judicious attendant. Everything indeed should be done to avoid the infliction of discomfort on the hyperæsthetic senses, to calm irritability, and to promote rest. If the limbs be cold, they should be kept at an equable temperature by means of flannel or other warm clothing. The headache which is so often present may be relieved by the temporary application of evaporating lotions, or ice, to the forehead or shaven scalp; and, for the same and other purposes, it may even be advisable to apply leeches behind the ears, or blisters, or other counter-irritants to the temples, scalp, or back of the neck. Leeches, however, as a rule, should only be used early in the disease. The number to be employed, and the amount of blood to be removed, must be determined partly by the age of the patient, partly by the other circumstances of the case. Thus, if the meningitis occur in a healthy-looking adult, free removal of blood even by venesection will be well borne, and may be highly beneficial. In a young child two or three leeches are generally ample. The relief of head symptoms is often attended with alleviation of sickness. But this may

sometimes be treated directly with advantage by the administration of either ice, bismuth, hydrocyanic acid, oxalate of cerium, or other remedies which are ordinarily given to assuage sickness. It is generally highly important to keep the bowels freely open, and this (in consequence of the extreme obstinacy of the constipation) is sometimes exceedingly difficult to effect. Enemata may be resorted to; but it is generally better to give purgatives by the mouth, and especially to give those which are not likely to upset the stomach. Sir T. Watson recommends as the best purgatives for children calomel and jalap, or calomel and scammony. Castor oil also generally agrees well with children. In the case of adults purgation should be actively employed. Amongst special remedies may be enumerated: first, simple saline or febrifuge medicines, which doubtless have little efficacy; and second, iodide of potassium, which is probably advocated rather on theoretical grounds than from actual experience of its value. Opium is generally considered to be contra-indicated; we must confess, however, that we have not unfrequently administered it during the earlier stages of meningitis, not only without obvious injury to the patient, but with manifest relief to his irritability and insomnia. Fluid nutriment should be administered in small quantities, and at frequent intervals.

Prophylactic measures are of paramount importance in the case of either children or adults in whom there is reason to fear the supervention of meningitis. Their studies or other mental labours should be intermitted; they should be kept quiet in mind and body, should keep early hours, be removed (if need be) to some healthy locality, occupy well-ventilated rooms, have ample wholesome nourishment, and be placed under a course of cod-liver oil and tonics. Further, all their functional disturbances should have due attention paid to them, sickness should be obviated, constipation overcome.

Adults as a rule may be treated far more actively than children, and those who are non-tubercular far more actively than those who are tubercular. For such patients the main remedies during the attack consist in cold to the head, leeching behind the ears, and active purgation.

As regards the *treatment of spinal meningitis*, it is essential: that the patient be kept in the recumbent posture on a suitable bed; that he be kept scrupulously clean and dry; that all parts liable to bed-sores be defended from the effects of pressure; and that the condition of his bladder and bowels be carefully watched, and the bladder, if necessary, relieved periodically by the catheter. In other respects the remedial measures to be employed are the same as those which are supposed to be serviceable in cerebral meningitis.

---

## IV. ENCEPHALITIS AND MYELITIS

*Inflammation and Suppuration of the Brain and Cord*

*Causation.*—The circumstances which determine acute inflammation in the brain and cord are, like those which cause inflammation elsewhere, very various. In many cases it is due to extension from without: spreading directly from the pia mater, or (in most cases in which pus is extravasated into its cavity) from the arachnoid; or following upon inflammation originating in the dura mater or the bones of the skull or spine; or referrible to the direct spread in depth of erysipelatous and other like affections of the skin and subjacent tissues. In a large number of cases encephalitis or myelitis arises from the influence of some irritating mass (such as a clot, tumour, parasite, or patch of softening), situated in the nervous substance or implicating it from without. It is a common consequence of injuries, even if these be unattended with fracture. It is sometimes referrible to pyæmia. And not unfrequently it is an idiopathic affection, due to exposure or to causes which we fail to recognise.

*Morbid anatomy.*—1. *Encephalitis.* There is no reason to doubt that inflammation occasionally involves the great bulk of the brain, as it certainly sometimes does the whole thickness of the cord in no inconsiderable proportion of its length. The cases in which this phenomenon is believed to have been present are those in which the general substance of the brain has been found after death much congested and softened, and in which the inflammatory process, if present at all, must have been in quite its initial stage. The condition, in fact, has differed little from what is seen in general congestion of the organ, as it is sometimes observed in fatal cases of epilepsy, delirium tremens, or sunstroke. In most cases of encephalitis the inflammation is of limited extent, occupying sometimes tracts of grey matter, sometimes tracts of white, and often involving portions of both. In some instances a single patch is present, in some there are several; and their sizes and forms vary within wide limits. If, however, they be not determined as to shape and extent by the fact of their being secondary to some clot or other adventitious mass, or to meningeal inflammation, they tend to assume a roundish or ovoid form, rendered more or less irregular by the configuration of the surface of the brain and the arrangement of its parts. The changes which mark the early stage of acute inflammation are more or less circumscribed congestion, effusion of fluid and other inflammatory products, and softening. The tissues of the affected part are swollen and pulpy, and generally admit of being readily washed away under the impulse of a stream of water, leaving a shreddy excavation behind. The redness is more or less intense according to the quantitative relation the congested vessels have to the amount of exudation, and is generally patchy. Sometimes small extravasations of blood occur. Further, more or less congestion and œdema, together with some yellowness of tint, may generally be observed in the surrounding tissues.

With the progress of the inflammatory process, exudation-corpuscles or pus-cells accumulate in the affected district, which gradually loses its congested aspect and gets yellowish or greenish, and less and less consistent. Presently the central portion becomes diffuent, and an abscess forms; the pus of which is thick, glairy, yellowish or greenish, and occasionally offensive, and the parietes of which are constituted by the still solid but soft and breaking-down tissue. Occasionally the abscess becomes encysted, the capsule sometimes attaining a thickness of a quarter of an inch. The microscopical characters of the inflamed patches vary somewhat according to the stage at which the process has arrived. In the early periods there may be observed: vascular changes with accumulation of leucocytes in the perivascular sheaths; destruction of the nervous elements—the myeline of the nerve-tubules breaking up into globules of various sizes; and development of granule-cells. Somewhat later the degenerating tissue becomes loaded with pus-corpuscles. In the fully-formed abscesses, the puriform matter is not unfrequently found devoid of pus or other cells, and comprising only fatty matter and débris of tissue.

Abscesses of the brain are not of very frequent occurrence, and are mostly solitary. When multiple, they are almost always pyæmic. The abscesses of most interest to the physician are those which are secondary to disease of the ear, nose, orbit, or other parts of the skull. When secondary to ear-disease, they occur either in the adjoining part of the middle or posterior cerebral lobe, or in the corresponding lateral lobe of the cerebellum, or somewhat more rarely in the pons Varolii. In most instances the surface of the bone is carious, the dura mater over it is softened and inflamed, and the abscess is situated in a diseased patch of brain, which has become adherent; but occasionally the dura mater remains apparently healthy, and the abscess moreover is separated from the surface by a layer of healthy-looking brain substance. The explanation of this fact is not clear; but it is generally assumed to be due to the plugging of some of the vessels passing from the sinuses into the substance of the brain, or to the extension of inflammation along them. According to Sir W. Gull's and Dr. Sutton's statistics, it appears that abscesses occur equally on both sides of the brain; and that, although any part may be their seat, they are most common in the middle cerebral lobes. The presence of an abscess of medium or large size in the substance of the brain causes general enlargement of the lobe or part in which it occurs, with flattening of the surface of the brain over it and in its vicinity, obliteration of the sulci, and displacement of the subarachnoid fluid. An occasional result of abscess is its extension, by bursting or by gradual erosion, into the cavity of the arachnoid, or into one of the ventricles, or its discharge externally through the ear or nose.

2. *Myelitis*.—Inflammation of the substance of the cord is attended with similar changes to those above described. When secondary to disease of the membranes it first involves the white substance, and only subsequently, and at a comparatively late period, extends to the central grey

columns. Idiopathic inflammation, however, mostly affects primarily and principally the grey matter. It results in softening of the nervous tissues, with a much more marked liability to the extravasation of blood than attends cerebral softening; indeed, in Charcot's opinion, hemorrhage (however copious) into the substance of the cord is mostly, if not always, the result of previous inflammatory softening. Inflammation generally tends to implicate the whole thickness of the cord, and, though frequently limited to comparatively short lengths of it, not very uncommonly involves extensive tracts. It sometimes occurs in scattered patches; and not unfrequently has a tendency to spread. Actual abscesses are of rare occurrence.

*Symptoms and progress.*—1. *Encephalitis.* The symptoms which may be referred to inflammation of the brain-substance extend no doubt over a wide range. Indeed, it is unquestionable, as has already been pointed out, that many of the symptoms of cerebral meningitis are really due to implication of the subjacent grey matter. Further, these conditions are so generally combined that it would be a mere waste of space and of ingenuity to endeavour to make any absolute distinction between them.

Of acute general inflammation of the encephalon there is little to be said. The cases are rare, the symptoms which they present are vague, and the morbid changes which are observed after death are, to say the least, obscure. They are mostly of rapid progress, and attended, as Dr. Wilks observes, with pyrexia, delirium, dulness of intellect, and final coma, but perhaps no other symptoms specially referable to the brain. Occasionally there is a preliminary stage in which, as he says, the patient may suffer from headache, sickness, slow pulse, and constipation. These are symptoms which are not unfrequently met with in cases of sunstroke, and occasionally in persons who have been indulging continuously, for some days or weeks, in excessive drinking.

The symptoms which attend inflammation secondary to the presence of apoplectic clots, patches of softening, tumours and the like, in the substance of the brain, are also exceedingly vague. A little accession of fever, a little increase of headache or giddiness, a little failure of appetite, a little aggravation of the paralytic phenomena from which the patient has been suffering, a little impairment of intelligence, the occurrence of delirium, convulsions, or coma, and perhaps the development of some rigidity in the affected limbs, some hyperæsthesia, some pain in muscles or joints, or some tendency to the formation of bed-sores on the affected side, separately or in combination, are the main indications of its supervention.

The symptoms due to circumscribed inflammatory softening, or supuration, are not less vague and obscure than those which belong to the varieties of inflammation already considered. Among those which may be present are febrile disturbance with rigors, anorexia, vomiting, and constipation, vertigo, headache often occurring—mainly at one spot, dulness, stupidity, delirium, coma, epileptiform convulsions, paralysis, affection of speech or of the special senses, and want of control over the bladder and rectum. In addition, few if any of the other symptoms which may be

observed in cerebral meningitis may not at one time or another, or in certain cases, be present here. On the other hand, an abscess may be found encysted in some part of the brain-substance, which has existed there for weeks or months, possibly years, without giving any hint of its presence. It is obvious, indeed, when we consider the various sizes which inflamed regions or abscesses present, the various positions which they may occupy in the substance of the encephalon, and the various lesions (pyæmia, disease of the ear, and inflammation of the dura mater, pia mater, or both) with which they are apt to be associated, that the symptoms which accompany them must present the greatest possible variety. Thus, as regards febrile symptoms, there can be little doubt that the inflammatory process in the brain will usually be attended with more or less marked fever, and not improbably with rigors, but that these phenomena will certainly be aggravated if pyæmia be present, or if suppuration be taking place beneath the dura mater, or pus have escaped thence into the cavity of the arachnoid; while, on the other hand, they may be entirely absent if the patch of inflammation be small, or if it pass into the chronic state or form an encysted abscess. Again, pain is one of the most common symptoms of abscess of the brain: pain, various in character, often referred to a particular spot, sometimes affecting the eyes, or shooting through the temples, or occupying the back of the head; but pain may be absent from first to last and generally, when it is present in any marked degree, is due rather to co-existent affection of the bones or dura mater than to the cerebral disease. Another frequent consequence of localised inflammation or abscess is paralysis or interference with the functions of one or other of the nerves of special or common sensation. But while it will be admitted that an extensive lesion will probably cause hemiplegia on the opposite side of the body, it is obvious that the presence of hemiplegia, and especially of affection of any one nerve, or group of nerves, will depend less on the size of the lesion than on its situation. If it be seated in the pons Varolii or medulla oblongata, a wide extent of paralytic affections of the spinal nerves will almost necessarily ensue, and respiration and deglutition be largely interfered with. The importance, however, of analysing the complex nervous symptoms which may be present, in reference to the facts of cerebral localisation, with the object of determining the locality of the lesion, is sufficiently obvious. The evidences of optic neuritis may often be observed in these cases.

There are, indeed, no special symptoms, or groups of symptoms, the presence or absence of which will enable us to diagnose the presence or absence of a patch of inflammatory softening or of an abscess in the brain. We have good reason, however, for suspecting the presence of such lesions when symptoms of the kind above enumerated supervene in the course of chronic otorrhœa, or of syphilitic or other forms of caries or necrosis of the bones of the skull, or upon injuries to the skull or brain. Yet, even here, the symptoms which we take to be indicative of cerebral abscess may be due to suppuration beneath the dura mater, with extension to the arachnoid or pia mater.

The beginning of circumscribed inflammation or suppuration of the brain is marked sometimes by a sudden attack of convulsions, sometimes by unilateral or more limited loss of power or sensation, sometimes by cephalalgia with vertigo and vomiting, sometimes by impairment of intelligence, sometimes by fever. The pulse, as in other cerebral affections, is not unfrequently slow and irregular. The progress of the disease, like that of meningitis, may often be divided into a stage of irritation and one marked by impairment or abeyance of the functions of the nervous centres, passing into collapse. In the former, we may observe vertigo, headache, intolerance of light, hyperæsthesia, irritability, wakefulness, with perhaps delirium and vomiting; in the latter, disappearance of pain, paralysis, want of control over the action of the bladder and rectum, drowsiness, stupor, coma. Convulsions may occur at any time; but, we repeat, the symptoms are variable in the highest degree, both as to their nature and as to the order of their succession; many who have abscess of the brain die without the presence of abscess having ever been suspected; and many cases, in which we venture to foretell that abscesses will be discovered, falsify our prediction upon the post-mortem table. Reckoning the duration of cases from the time when acute symptoms indicative of brain disease first manifest themselves, they may be said to prove fatal usually from the fifth or sixth day down to the end of the third or fourth week. Death is commonly preceded by coma, but may be due to asthenia or to asphyxia.

2. *Myelitis*.—The symptoms of acute myelitis are, in the main, those of paraplegia of rapid development, and are therefore in many respects like those of spinal meningitis. In considering the symptoms due to myelitis there are two or three considerations which it is important to bear in mind. In the idiopathic affection the inflammation affects primarily, and in the highest degree, the central grey matter of the cord; hence it follows that sensation will probably be at least as soon and as profoundly involved as motion. In meningitis and other diseases affecting the cord from without, the white matter is mainly implicated, and motion is lost in far higher proportion than sensation. In myelitis there is a great tendency for the disease to diffuse itself throughout the length of the cord, and thus not merely to cause gradually ascending paralytic phenomena, but also to annul the reflex functions of the cord, and the faradic contractility of a gradually increasing number of muscles. The result is different, as we know, when paraplegia follows any limited lesion of the thickness of the cord. In myelitis the profound involvement of the elements of the grey matter naturally tends rapidly to induce the peripheral nutritive consequences of spinal lesions, especially wasting of muscles, development of bed-sores over the sacrum and elsewhere, and inflammation of the bladder and kidneys. In this respect especially idiopathic myelitis far more resembles the effects of serious accidental injuries to the spine and cord than any other form of disease. Further, the grey matter of the cord is, so far as we know, insensible to pain, and lesions which directly involve it are also unattended with pain.

Myelitis is not, therefore, usually a painful disorder; pain, indeed, in spinal affections is almost always the consequence of pressure upon, or involvement of, the sensory nerves within the spinal canal, or of the posterior roots in their passage through the white matter of the cord. Hence pain in the back, extending to the trunk or extremities, is much less likely to be due to myelitis than to meningitis, and, it may be added, less likely to be due to meningitis than to the growth of tumours or the extension of aneurysms. Lastly, twitchings and tetanic spasms of the muscles are in no sense an indication of myelitis. They are common, however, in meningitis.

The symptoms of acute myelitis sometimes come on gradually in the course of a few days, sometimes manifest themselves with almost sudden intensity. A patient, perhaps after long-continued over-exertion or exposure to the weather, or sleeping on the damp grass, or it may be during the progress of vertebral caries, is attacked in his toes and feet with numbness and tingling, which gradually extend upwards, and are succeeded after a varying interval by the progressive or sudden annihilation of sensation or voluntary motion in the lower extremities and up to the level of a horizontal line which corresponds to the upper limit of the distribution of the involved spinal nerves. The relative dates at which sensation and voluntary motion are lost vary in different cases, as also does the degree in which the corresponding limbs are involved. Nor does it necessarily follow that either sensation or motion is wholly abolished. There is not usually absolute pain, still less pain of a neuralgic character; but there is often a distressing sense of restlessness and tingling in the paralysed limbs, and of constriction round the abdomen and chest. There may, however, be cutaneous hyperæsthesia at the upper limit of the affected region. Twitchings of the paralysed muscles may attend the earlier stages of paralysis; but generally these soon cease, and the directly implicated muscles, as a rule, speedily lose their faradic contractility, and become flaccid and lifeless. The muscles, however, thus affected are only those supplied by the diseased length of cord; they are hence few or many, according to circumstances; while all those which are supplied by nerves given off lower down retain this and their reflex excitability and their bulk, as in ordinary cases of paraplegia. Priapism is occasionally present; the bowels are constipated, and the motions discharged unconsciously; and there is either retention or incontinence of urine. Bed-sores, especially over the sacrum, are apt to arise, in spite of every precaution, sometimes within four or five days of the commencement of paraplegia; and at the same time, even where the greatest care has been taken, the urine probably becomes ammoniacal and the mucous membrane of the urinary tract inflamed.

It need scarcely be added that the distribution and extent of the paralytic phenomena will be determined by the position and extent of the disease; that there will be involvement of the lower limbs only when the disease occupies the mid-dorsal region, of the upper and lower extremities when the cervical enlargement is included; that there will be hemiparaplegia when one side of the cord mainly suffers, difficulty of respiration

when the intercostal nerves are implicated, asphyxia when the origins of the phrenic nerves are also involved. In the last two cases difficulty of speech and inability to discharge accumulating mucus from the bronchial tubes add seriously to the patient's sufferings. It must not be forgotten that myelitis is apt to spread, and that hence the medulla oblongata may become implicated, and bulbar symptoms be added to those due to the affection of the cord. Optic neuritis occasionally attends myelitis; and in one case under our care optic neuritis, causing complete blindness, preceded an attack of myelitis which proved fatal.

It is important also to note that myelitis, whether it involve much or little of the cord, is sometimes of little intensity and productive of slight symptoms; that the patient may complain only of a little coldness or numbness, or of slight weakness in one or more of the extremities, or of impairment of control over the rectum or bladder, and recover in the course of a few days or weeks without any further trouble.

Although cerebral symptoms, neuralgic pains, and spasmodic action of the muscles are no necessary parts of myelitis, they are not uncommonly superadded in consequence of the co-existence of some degree of meningeal inflammation and brain implication. Further, marked fever is often present, which may be attended with remissions, rigors, and sweats.

Acute myelitis varies greatly, not only in the severity of its symptoms but in its danger. In many cases, especially where the cord is extensively involved, death occurs in the course of a few weeks, often in the course of a few days. Yet even after severe attacks life may be prolonged almost indefinitely with persistence of paralytic symptoms. In a large proportion of cases recovery is incomplete, and the patient remains crippled for the remainder of his life. In some of the more severe cases, and in most of those in which the symptoms are slight, perfect restoration to health ensues. The causes of death are various. The patient frequently dies, however, of asthenia, which may be largely determined by secondary affections of the skin and urinary passages; or of asphyxia referrible to implication of the respiratory nerves.

*Treatment.*—For the treatment of inflammation of the substance of the brain little or nothing can be done directly. We may, if the symptoms be severe and their onset sudden, have recourse to the classical measures:—namely, cold to the head, in the form of evaporating lotions, affusion, or the ice-bag; purgation by means of active drugs, and especially of such as cause watery evacuations; and the abstraction of blood, preferably by leeches, from the temples or behind the ears, or by cupping at the nape of the neck. It must be admitted, however, that these measures are not often of any obvious utility. For the most part the same general treatment may be employed here as has already been suggested for meningitis. But if the affection be traceable to inflammation of the ear, or disease of the bones of other parts of the skull, the question of surgical interference will naturally arise.

For the treatment of myelitis we must also refer to remarks which have been previously made under the head of spinal meningitis.

## V. SYSTEM DISEASES DEPENDENT ON ACUTE INFLAMMATION, ON CHRONIC INFLAMMATION OR SCLEROSIS, AND ON DEGENERATIVE CHANGES

The affections which we shall consider under the above heading form a very interesting clinical group, which was originally studied and unravelled mainly by Duchenne, Vulpian, and Charcot in France, by Todd, Gull, and Lockhart Clarke in our own country, by Brown-Séquard, and has since been investigated and elucidated by many other observers both here and abroad. They are probably all of inflammatory origin, and although in all cases the result is overgrowth with induration of the neuroglia, and degeneration of the nervous elements, they present at least three different modes of origin. In one case the inflammation is of sudden onset and acute, and marked by hyperæmia, extravasations of blood, swelling of the neuroglia, and inflammatory exudation; in another case the changes are of slow progress, even from the beginning, and have some resemblance to those occurring in cirrhosis of the liver; while in a third case there is reason to believe, as Charcot taught, that the morbid change (whether it be inflammatory, as some believe, or degenerative, as others maintain) begins in the nerve-cells, in which case it may either continue strictly limited to them, or gradually involve the surrounding connective tissue to a greater or less extent.

The term sclerosis may be conveniently applied not only to that affection in which the morbid process consists from the beginning in a slow overgrowth and induration of the neuroglia, but also, for the reasons above given, to the later stages of the acute inflammatory disorder, and of the degenerative process starting from the nerve-cells.

In most cases the first visible evidence of disease would seem to consist in an overgrowth or hyperplasia of the neuroglia, indicated by the appearance in it, and in the perivascular spaces, of a greater or less abundance of the cells characteristic of embryonic tissue, together with an increase of the amorphous intercellular substance which takes part in the constitution of the neuroglia, and enlargement of the vessels. At this stage the affected tracts of tissue are somewhat swollen, but their nervous elements present little, if any, evidence of disease. As the morbid process advances, however, the hypertrophied neuroglia contracts and hardens, its new-formed cells get small and indistinct, the originally amorphous matrix assumes a delicate fibrillated character, and the blood-vessels become thick-walled and their channels narrowed. Moreover, the nerve-tubules and nerve-cells of the diseased regions now undergo important changes. When the sclerosis is situated in the white substance of the cord or brain, the nerve-tubules are seen to be more widely separated from one another than natural, the width of the intervals between them depending of course on the quantity of adventitious matter which has accumulated there. The tubules for the most part diminish in thickness, mainly in consequence

of the partial disappearance of the white substance of Schwann, and sometimes become moniliform; but intermingled with such tubules others may generally be observed which are either of normal thickness or are actually increased in diameter from swelling of the axis-cylinder. In the most advanced conditions of disease the nerve-tubules are greatly atrophied, and in many instances wholly deprived of their myeline sheaths; but they are rarely, if ever, absolutely destroyed. When the sclerosis occupies the grey matter, as, for example, the anterior cornua of the cord, we find, in addition to atrophy of the nerve-tubules, corresponding changes in the nerve-cells. In some instances, as Charcot points out, they become swollen, and, it may be, enormously enlarged, faintly granular and opalescent; and at the same time their processes appear thickened and twisted. These changes, which he ascribes to irritation, belong to the early period of the disease. Much more commonly the changes observed are of an atrophic character. In some cases the cells undergo pigmentation, diminish in size, and assume a rounded form, their processes at the same time becoming attenuated and shortened; and after a while they get reduced to simple roundish accumulations of pigment, and finally perhaps wholly dissipated. In other cases no pigmental deposit takes place, but the cells shrink in all their dimensions, each one drying up, as it were, into a kind of mummy. The processes partake in this change, and disappear in a greater or less degree. Corpora amylacea are usually abundant in sclerotic tracts; and Lockhart Clarke has described as sometimes present in them irregular patches of disintegration, from which all traces of the normal elements of the part, whether neuroglia, blood-vessels, nerve-tubules, or nerve-cells, have disappeared.

Sclerotic change is indicated, as to its coarser features, by a greyish translucent aspect of the affected part, with induration, and, according to the length of time it has been in progress, either slight tumefaction, or a greater or less degree of contraction. Further, there is usually close adhesion of the affected part to the pia mater over it, and some equivalent change in the pia mater itself. In most cases death occurs at an advanced period of the disease, and hence induration and diminution of bulk are generally observed.

The morbid processes under consideration have a remarkable tendency to be limited in certain cases to definite tracts or regions of the nervous centres, and then comparatively rarely transgress these limits. Thus certain cases (infantile and adult spinal paralysis, and progressive muscular atrophy) are characterised by the limitation of disease to the anterior cornua of the grey matter of the cord, or more exactly (in many cases) to the groups of large nerve-cells therein situated—involving these parts, it may be, in their entire longitudinal extent, and rarely extending horizontally beyond them; other cases (lateral sclerosis) are distinguished by the sclerotic change having its special seat in the lateral white columns, which are then usually symmetrically affected in a considerable part of their length; other cases again (locomotor ataxy) are peculiar in the fact that the sclerosis involves mainly and often exclusively the posterior white columns, or rather

perhaps the outer bands of these columns, the fasciculi of Goll often escaping; while sometimes (glosso-labio-laryngeal palsy and ophthalmoplegia) the motor nuclei of the medulla oblongata are the special seat of disease; and at other times (disseminated sclerosis) the sclerotic change is scattered irregularly in patches throughout the nervous centres.

*A. Infantile Spinal Paralysis (Infantile Paralysis. Essential Paralysis. Acute Anterior Poliomyelitis)*

*Definition.*—By these terms is known a peculiar paralytic affection coming on in young children, with acute symptoms, and for the most part with fever, and ending speedily in rapid atrophy of certain muscles or groups of muscles, and permanent paralysis.

*Causation.*—Infantile paralysis may, according to the statistics of M. Duchenne (fils), come on at any time from birth up to ten years of age. But the great majority of cases occur during the second year of life. Its causes are obscure; it seems, however, neither to be hereditary nor to be dependent in any degree on privation or other conditions associated with poverty. Dentition would appear to be largely concerned in its causation, and it has often been observed to follow on measles, 'gastric fever,' and other febrile maladies. Exposure to cold and damp is undoubtedly a common cause of the disease.

*Morbid anatomy.*—The morbid processes of infantile paralysis concern the spinal cord, the motor nerves, and the organs of locomotion. Few examinations have been made during the earlier stages of the disease. It appears, however, that at this time there are evidences of acute inflammation limited to the anterior horns, and indicated by undue redness with congestion of blood-vessels, small extravasations of blood, and swelling of the neuroglia and ganglion cells. We are much better acquainted with the morbid anatomy of the disease after it has become chronic. At this time, also, the only lesions usually observable in the cord occupy the anterior cornua. They consist mainly in pigmental degeneration and atrophy of the groups of large cells, which tend ultimately to disappear completely. Herewith, however, is usually associated more or less sclerotic change in the tissues in which these cells are imbedded. The affection is obviously inflammatory, and, although commonly involving the neuroglia

FIG. 104. Diagram to show seat of lesions in infantile paralysis. Area of disease represented by transverse shading.

as well as the nerve-cells, is sometimes limited to the cells, or to these and the portions of neuroglia immediately surrounding each. Whence Charcot regards the inflammatory process as commencing in the nerve-cells, and as implicating the neuroglia secondarily only. The morbid process affects the various regions of the anterior cornua indifferently, and by no means necessarily symmetrically; it may involve them in patches, or uniformly throughout a considerable vertical extent. The diseased cornua ultimately shrink in proportion to the degree and duration of the morbid process.

The motor nerves are involved secondarily to the spinal cord and only

at a comparatively late period of the disease. They undergo atrophy, the ultimate tubules diminishing in size and tending to lose their myeline sheaths. The implicated muscles shrink rapidly. In the first instance the only obvious and constant changes are a diminution in the diameter of the fibres, hyperplasia of the cells of the sarcolemma, and, according to some observers, overgrowth of the intervening connective tissue. But even in the early stage a few muscular fibres will often be found to have lost their transverse striation and to have become granular. At a late period of the disease the atrophy of the fibres has become more complete, and they then not unfrequently, but by no means necessarily, present well-marked fatty degeneration. At this time, also, there is often marked increase of the intervening connective tissue, and sometimes a large accumulation of fat. The consequences, as regards the general form and bulk of the muscles, are various: in some cases they appear simply shrunk to an extreme degree; in other cases they are found to retain their normal size and shape; and occasionally they present a positive increase of bulk, owing to the accumulation between their fibres of adipose or fibrous tissue.

*Symptoms and progress.*—The onset of infantile paralysis is usually sudden and marked by fever, occasionally attended with convulsions, coma, or other cerebral symptoms. The duration of this febrile attack—which, however, is not always present—varies from a few hours to a couple of weeks. The paralytic condition of the muscles for the most part comes on quickly and unexpectedly. Sometimes the child is found paralysed on waking up from sleep; sometimes on the subsidence of coma or convulsions, or on the disappearance of some specific fever or of the special fever of the disease, or in the course of that fever. The paralysis increases rapidly from the moment of its first appearance, so that at the end of a day or two, sometimes however after a longer interval, it has attained its maximum degree and extent. Its extent varies of course in different cases: sometimes both arms and legs are uniformly and completely paralysed; sometimes the legs only; sometimes the arm and leg of one side; sometimes a single extremity; and sometimes, and on the whole more commonly, groups of muscles belonging to one limb or to several limbs or even to the trunk. The arms alone are rarely attacked. The paralysis is marked from the first by flaccidity of the muscles, and abolition or impairment of reflex excitability and of so-called tendon reflexes. Moreover (and this is a point of capital importance), great diminution or absolute abolition of faradic contractility rapidly supervenes in the affected muscles, so that at the end of five days, or it may be a week, many of the muscles may have entirely ceased to contract under the influence of faradism. The reactions of degeneration follow (see p. 1003). Occasionally pain in the back, pain on movement of the limbs, and tenderness of muscles, attend the commencement of the disease; but these phenomena form no essential feature of its clinical history, and in a large number of cases are wanting. According to Dr. West, cutaneous hyperæsthesia is present at this time, and may continue for several weeks; but this is far from being a constant phenomenon. Indeed, it may be regarded as characteristic of the disease

that absolute paralysis of certain muscles, attended with flaccidity and loss of reflex and faradic contractility, is linked with retention of cutaneous sensibility, perfect control over the rectum and bladder, entire lack of all tendency to inflammation of the urinary organs, formation of bed-sores, or appearance of cutaneous eruptions, and almost total absence of pain. The first stage of the disease characterised by the phenomena just enumerated lasts from two to six months—sometimes, however, longer, sometimes shorter—and is then followed by the second stage, which continues probably for another six months. During this stage more or less amendment generally takes place; certain of the paralysed muscles, and more especially those in which faradic contractility had not been wholly abolished, slowly regain their normal reflex and electrical properties, and their power of spontaneous movement; a greater or lesser number, however, of the muscles which had lost their faradic contractility probably remain (singly or in groups, or occupying the whole of one or more limbs) permanently paralysed; and not only remain paralysed, but undergo more or less rapid atrophy. Any improvement, excepting in those muscles which are already in progress of amendment, can scarcely be hoped for after the lapse of eight or ten months from the commencement of the disease.

The changes which now slowly ensue are interesting. In the first place the permanently paralysed muscles, which had already perhaps given indications of shrinking at the end of a month from the beginning of the disease, rapidly become atrophied—generally undergoing much reduction in size, but sometimes retaining their natural bulk in consequence of overgrowth of interstitial connective tissue and fat. They continue limp, and wholly impassive under the influence of every kind of stimulus. In the second place, it often happens that the bones of the affected members become arrested in their development, and are consequently at the time of full growth thinner and shorter, sometimes considerably shorter, than they should be. This result has been observed several times by Volkmann in cases in which the primary disease was of short duration, and paralysis had wholly disappeared. In the third place, the paralysed limbs show a striking and permanent diminution of temperature, a diminution which is more marked than in any other form of paralysis. It appears to be connected with a general diminution in the bore of the blood-vessels. In the fourth place, various deformities, mainly of the hand and foot, are apt to ensue. These generally begin to show themselves about the end of the first year, and depend apparently on the unequal degrees in which opposing muscles are affected, and on the predominant action therefore of the healthy or less completely paralysed muscles. Their production is largely aided by the remarkable laxity of the ligaments, which is also usually present in these cases. The most common deformity of the foot is talipes equinus.

Cases of infantile paralysis occasionally depart from the type above sketched. Sometimes the disease lasts for a few days or weeks only, and complete restoration to health ensues; sometimes the paralysis, instead

of being developed with sudden intensity, creeps on gradually and attains its full development only after some length of time; sometimes, again, the patient suffers from occasional exacerbations or relapses.

*Treatment.*—In the early stage of infantile paralysis, treatment must be mainly expectant. Salines, laxatives, and other febrifuge medicines may be used with some advantage, and in some cases perhaps counter-irritation, or the abstraction of blood by leeches or cupping-glasses applied in the course of the spine. The patient should, of course, be kept absolutely at rest, and careful attention should be bestowed in order to relieve symptoms and obviate the occurrence of complications. But, after all febrile symptoms have passed away, and all acute inflammatory mischief has subsided, which will probably be at the end of three or four weeks, it will be necessary to adopt measures to promote the restoration of those muscles which are capable of restoration. The affected muscles may be divided into three categories: first, those which, though paralysed, have their faradic contractility but slightly affected; second, those in which the faradic contractility is much enfeebled or abolished, but which respond to galvanism; and, third, those which fail to react to any form of electricity. Muscles belonging to the first category tend to recover completely, independently of all treatment; but nevertheless the periodical application of faradism or galvanism to them tends to hasten their recovery. Muscles belonging to the second category for the most part undergo more or less considerable atrophy, which may continue to progress for many months, and may result in their permanent emaciation and weakness, even though complete restoration of the nerves and nerve-centres in relation with them ultimately takes place. In these cases the long-continued and systematic use of galvanism, especially if it be commenced early, will often serve to arrest the wasting of the muscles, and ultimately to bring them back to the condition of health. The prospects as regards the muscles in the third class are much more gloomy. They invariably waste rapidly, and in a very large proportion of cases fail absolutely to undergo any kind of improvement. Still, even here, the solicitous and long-continued use of galvanism sometimes succeeds in effecting important improvement. It need scarcely be said that the longer recourse to electric treatment is delayed, the less is the chance which it affords of benefit. Nevertheless, a case reported by Duchenne, in which the complete restoration of many muscles of the arm (which had been atrophied and had lost all electric contractility for a period of four years) was effected by means of faradism applied periodically during the space of two years, proves that we need not despair even when circumstances seem most adverse. An important result to be derived from electricity, even when it fails to cure absolutely, is the prevention of the deformities due to the unequal action of antagonistic muscles. In conjunction with electricity, other measures may be used to improve the condition of the muscles; among which may be enumerated exercise, rubbing, shampooing, baths, and mechanical measures to obviate the tendency of certain muscles to contract and cause deformity. Iron and

other tonics are, in a certain sense, useful. Strychnia has been largely recommended.

The treatment of the results of infantile paralysis belongs to the surgeon.

### B. *Adult Spinal Paralysis (Acute Anterior Poliomyelitis)*

Both Duchenne and Charcot have published cases (and, indeed, it seems probable that such cases are not uncommon) in which adults have been attacked with disease resembling in all essential particulars infantile paralysis. The recorded cases show: that it comes on in adults, as in children, with febrile symptoms, lasting, it may be, for a few days, and attended with or followed by motor paralysis of a greater or lesser number of voluntary muscles, but without implication of cutaneous sensibility, loss of control over the rectum or bladder, or tendency to the formation of bed-sores; that the muscles are flaccid, incapable of excito-motor action, and tend rapidly to lose their faradic contractility, and to waste; and that, after the paralysis has reached its highest degree, more or less amendment takes place in some of the muscles. It not uncommonly happens in the case of the adult, as probably happens also in the child, that pain in the spine, with forward curvature, and some degree of pain in the limbs and tenderness of the muscles, attend the onset of the disease. The chief point in which the history of the disease in adults differs from that of the disease in children is the necessary absence from it of all mention of the various deformities resulting from defective development: the bones do not become relatively short; and deformities connected with the joints are less extreme.

The pathology and treatment are the same as in the infantile disorder.

### C. *Acute Ascending Spinal Paralysis*

*Definition.*—This disease was first described by Landry in 1869, and is characterised by symmetrical paralysis mainly of motion, commencing for the most part in the feet, and spreading gradually but pretty rapidly upwards, until all the voluntary muscles are implicated, and (unless it be arrested in its progress) death ensues from asphyxia or inability to swallow; the paralysis being unattended by atrophy or impaired electric contractility of muscles, or by loss of control over the emunctories, and unconnected with discoverable lesions in the nervous centres.

*Causation.*—Very little is known on this head. It appears to occur mainly in persons between twenty and forty years of age, and in men more frequently than in women. It has been attributed to syphilis, and to exposure to cold and the like, and to long-continued alcoholic excess. And it has followed occasionally on specific fevers and acute inflammations.

Owing to the rapidly fatal character of Landry's paralysis in its typical form, and the absence of lesions sufficient to explain the remarkable symptoms of the disease, both Landry and Westphal have been inclined to attribute it to some toxic influence. There is some reason,

indeed, as has been already shown, to believe that in some instances, at any rate, it is a mere variety of hydrophobia resembling the dumb rabies of dogs and the corresponding affection in rabbits.

*Morbid anatomy.*—No morbid changes sufficient to explain the symptoms of the disease have been discovered after death, either in the brain, cord, or nerves, or in any other part of the body. In many cases the cord has been found apparently quite healthy. But in some cases congestion and even small extravasations of blood have been discovered in it. Acute enlargement of the spleen was observed by Westphal, and has since been recognised by other observers.

*Symptoms and progress.*—After vague premonitory symptoms of variable duration, which are said usually to precede the occurrence of the specific symptoms of the disease, paralysis begins in the feet, and in the course probably of a day or two (implicating first the muscles which move the toes and feet, then the posterior muscles of the thighs and pelvis, and lastly the anterior and internal muscles of the thighs) involves the whole of the lower extremities. The trunk or fingers are next attacked. From the fingers the paralysis mounts up the arms, affecting the scapular muscles, however, before those of the upper arm. The lower part of the trunk suffers for the most part before the upper; and the muscles last attacked are those concerned in respiration and deglutition, the tongue, and the muscles of the face. The paralysis, which commences with simple weakness, soon culminates in total loss of voluntary power; the muscles become flaccid, no rigidity or tremors manifesting themselves at any time; and the superficial and tendon reflexes rapidly disappear; but the electrical excitability of muscles and nerves remains as a rule unimpaired, and no wasting of muscles takes place, excepting such as results from disuse. The sensory nerves are scarcely if at all involved; there is often no doubt numbness and tingling of the hands and feet; but rarely any actual loss of feeling, or neuralgic pains. No nutritive lesions occur. Voluntary power is for the most part retained over the bladder and rectum; but owing to paralysis of the abdominal muscles the expulsion of their contents is performed imperfectly and with difficulty. The general health of the patient in other respects, and his mental functions, are unimpaired.

In some rare cases the paralysis takes a descending course, commencing from above and involving the lower extremities last.

The progress, duration, and event of the disease vary. It is generally fatal, death resulting from the usual consequences of bulbar paralysis. The paralysis may become general and destroy life in the course of two or three days. Occasionally the progress of paralysis is much slower, and death is delayed until the end of the third or fourth week. More frequently the disease reaches its maximum and the patient dies in from eight to ten days. Recovery may commence from any stage of the disease; and in those cases in which paralysis has become general the parts last affected recover first. Convalescence extends usually over many weeks, but ends for the most part in perfect recovery.

*Treatment.*—No specific treatment for this disease is known. The ordinary measures adopted for paralysis may be adopted here. During convalescence, the constant current, with strychnia and other tonics, may prove serviceable.

D. *Progressive Muscular Atrophy* (*Wasting Palsy. Chronic Anterior Poliomyelitis*)

*Definition.*—This disease is characterised by progressive atrophy commencing in certain muscles, usually those of one hand, next involving, as a rule, corresponding muscles on the opposite side of the body, and gradually spreading to other muscles of the limbs and trunk.

*Causation.*—Progressive muscular atrophy occurs both in children and in adults, and principally in males. Its causes are obscure. It has been traced apparently to exposure, to excessive bodily or mental exertion, and to violent emotion; but mainly it appears to be an hereditary affection. In almost all cases of its occurrence in children which have come under Duchenne's observation it appears to have been hereditary.

*Morbid anatomy.*—The pathology of this affection differs little from that of infantile spinal paralysis. The parts affected are in this case, as in that, the anterior cornua, the motor nerves which emerge from them, and the muscles which these nerves supply. The affection is limited in many cases to certain groups of large cells—the cells undergoing the various forms of degeneration which have already been described, and finally, it may be, disappearing altogether; or it may include with these changes a greater or less amount of sclerosis of the contiguous portions of the anterior cornua, and corresponding atrophy of the nerve-tubules. In the early stage the blood-vessels of the affected parts are enlarged and their walls thickened. The anterior nerve-roots, which are connected on the one hand with the diseased portions of the cord, on the other with the affected muscles, undergo similar changes to those which have been described in connection with infantile paralysis; but the degeneration is never so extreme or general, nor does it distinctly manifest its presence until the muscular atrophy has made considerable progress. The muscular change consists essentially in a mere attenuation of the muscular fibres, with more or less proliferation, of an abortive character, of the cells of the sarcolemma. Granular and fatty degeneration, with disappearance of the transverse striæ may supervene at a late period of the disease; but it is merely a secondary phenomenon, and has no special significance. Hypertrophy of the connective tissue investing the muscular fibres, and accumulation of fatty matter in the same situation, are not uncommon. The affection of the nerve-centres is distinctly inflammatory, and precedes and causes the lesions of the motor nerves and muscles.

*Symptoms and progress.*—Progressive muscular atrophy, unlike acute spinal paralysis, comes on insidiously. Its advent is unattended with fever or other obvious constitutional disturbance. Indeed, the first indication of its presence is, almost without exception, wasting and loss of power of some muscle or group of muscles. The muscular atrophy may

commence at any part, even in the dominion of certain of the cerebral motor nerves, but most commonly begins in the hand, especially the right hand, whence it spreads first to the corresponding muscles of the opposite side of the body, then to those of both forearms, and presently becomes distributed with more or less irregularity, but symmetrically, throughout the trunk and lower extremities.

When it takes the orthodox course, it is the muscles of the ball of the right thumb which are usually first affected. Then the muscles of the hypothenar eminence and the interossei suffer; and the hand acquires an almost pathognomonic claw-like form. Next the muscles of the forearm waste, with some irregularity as to the order of their wasting. Subsequently the muscles of the upper arm and shoulder suffer, the triceps for the most part retaining its normal condition longer than the others. The muscles of the trunk usually suffer coetaneously with those of the upper arm, but are involved irregularly. The usual order, however, of their involvement is, according to Duchenne: first, the trapezius (of which the lower portion suffers earliest); then successively the pectorals, the latissimus dorsi, the rhomboidei, the levator anguli scapulae, the extensors and flexors of the head, the sacro-lumbalis, and the abdominal muscles. When the atrophy has extended thus far, the muscles of respiration and deglutition usually become affected. The clavicular portion of the trapezius is the last of the muscles of the trunk to succumb. The lower extremities are involved subsequently to the arms and trunk, but their muscles are apt to suffer equally in degree with those of other parts. The muscles which are earliest affected are the flexors of the foot on the leg, and those of the thigh upon the pelvis.

Not unfrequently progressive muscular atrophy first shows itself among the muscles of the trunk, attacking sometimes the pectorals, sometimes the serratus magnus, sometimes the spinal muscles, sometimes those of the abdomen, and thence extending to the other trunk muscles and to those of the extremities. Its commencement in the lower extremities is exceedingly rare.

A curious circumstance is pointed out by Duchenne: namely, that when progressive muscular atrophy attacks young children, its invasion is marked by the effacement of some of the muscles of expression; that their aspect consequently becomes more or less idiotic; that their cheeks become flaccid and their lips large and pendulous; and further, that it is only subsequently, and it may be after the lapse of years, that the muscles of the trunk and those of the limbs partake in the atrophic change.

In addition to the fact that progressive muscular atrophy is a disease of an essentially chronic character, and tends from insignificant beginnings slowly to involve a large number of the voluntary muscles of the limbs and trunk, it presents several other remarkable features which help to distinguish it from acute spinal paralysis and from other spinal disorders to which in many respects it has a close resemblance. First, the enfeeblement of the affected muscles does not precede their atrophy; it follows upon

the atrophy, is due to it, and is proportional to it; and indeed the motor power is not wholly lost until a very late stage of the disease, or until the muscles have undergone complete atrophy. *Second*, the faradic contractility of the affected muscles remains unimpaired, or rather diminishes only in proportion to the effacement of the constituent muscular fibres, and never disappears absolutely until voluntary power is wholly lost, namely, when atrophy has reached its extreme degree. *Third*, a very common feature of the malady is the presence in the affected muscles of irregular vibratile movements of the individual fibres, which may be seen and felt, and which, when superficial muscles are under observation, yield to the eye an appearance as though innumerable slender worms were in active parallel progression under the skin. These fibrillar oscillations are occasionally so violent as to cause movements of flexion and extension in the fingers or other parts. They are not constant, and are usually evoked either by the patient's efforts to bring the muscles into action, or by tapping, pinching, or otherwise exciting them. They are not peculiar to progressive atrophy, although they commonly attend it.

Characters which are common to this affection and to acute spinal paralysis are a lowering of the temperature of the affected limbs, absence of spinal or neuralgic pain and of tendency to the formation of bed-sores or to the appearance of cutaneous eruptions, and retention of control over the emunctories. Cutaneous sensibility is generally retained. It is well to bear in mind that the wasting of muscles is often concealed by the presence of an excess of subcutaneous fat, and that hence the true condition of things can often be determined only after careful investigation.

The course of progressive muscular atrophy is always slow and irregular. It may appear in some of the muscles of the face or hand, and years may elapse before it extends either to neighbouring muscles or to the corresponding muscles of the opposite side of the body. Or it may invade the muscles of the arms or legs with comparatively great rapidity, and then a long interval of quiescence may ensue. It may even become arrested in its onward progress, never to be reawakened. Most commonly, however, it advances either uniformly or by fits and starts, until the patient becomes utterly helpless. The duration of the affection is very various. In many cases the patient survives for eight or ten years, or even for twice that period. And, indeed, there is nothing to interfere with the duration of life unless the muscles of respiration or those of deglutition get involved. If this happen, the patient is liable to be cut off either by inability to swallow, by choking, or by difficulty of breathing, and the pulmonary complications which are then so apt to ensue. If these important parts are early implicated, the patient may succumb within two or three years from the commencement of his malady.

*Treatment.*—The treatment of progressive muscular atrophy calls for no special observation. It may be the same that has been recommended for the chronic stages of acute spinal paralysis, and especially the systematic use of electricity to the affected muscles. M. Duchenne, who strongly urges the beneficial influence of this treatment, says that the

progress of the disorder may sometimes be arrested, and muscles not too far advanced in atrophy may occasionally be restored by it. He prefers faradism applied in turn to each affected muscle, but recommends also the concurrent use of the direct current—constant or interrupted. He specially advocates the solicitous treatment of those muscles which are the most important either for the maintenance of life or for the usefulness of the limbs. The following are some of the rules which he lays down. The more a muscle is atrophied, its contractility diminished, and its sensibility benumbed, the longer it should be subjected to stimulation, the more intense should be the current, and the more rapid its intermissions. But when sensibility returns it is prudent to diminish the intermissions, and abate the intensity of the current, and even to abridge the number of sittings, lest unmanageable neuralgia be provoked. No sitting should be prolonged beyond ten or fifteen minutes, and rarely more than one minute should be given to each muscle.

#### E. *Lateral Sclerosis (Spasmodic or Spastic Spinal Paralysis)*

*Definition.*—The affections which it is intended to comprise under the above designations are mainly those to which M. Charcot applies the names of ‘*amyotrophies spinales deutéropathiques*,’ ‘*sclérose latérale amyotrophique*,’ and ‘*spasmodic tabes dorsalis*.’ They are characterised, first, as regards their morbid anatomy, by a sclerotic change affecting the lateral white columns of the cord, for the most part symmetrically and in their whole length, and in many cases extending thence so as to involve more or less of the anterior cornua, and occasionally of the sensory elements; second, as regards their clinical phenomena, by paralysis of the limbs, with rigidity and tendency to contract, associated sometimes with wasting of muscles, sometimes with neuralgic pains.

*Causation.*—The causes of the inflammatory process which induces sclerosis in the lateral columns are various. It is a common consequence of effusion of blood into the substance of the cerebrum, or of the presence of a patch of softening, and equally follows any destructive lesion of the crura, pons, medulla oblongata, or spinal cord; and in this form is not unfrequent in early childhood. It is sometimes also of idiopathic origin, under which circumstance it does not appear to be hereditary, and comes on mainly between the ages of twenty-five and fifty. The causes of the idiopathic disease are obscure; it has been referred, however, to the influence of cold and wet, and to injury.

*Morbid anatomy.*—The simplest form of lateral sclerosis, both pathologically and clinically, is that which occurs secondarily to some cerebral or other lesion. We have already drawn attention to the fact of its occurrence under the conditions here specified. In connection with hemorrhage or softening involving the motor region of one of the cerebral hemispheres a tract of degeneration may after a time be traced along the crista of the corresponding crus cerebri, through the pons, into the anterior pyramid, and along the decussation to the opposite side of the cord, in which it occupies almost exclusively the lateral white column.

being separated, however, from the surface by a persistent lamina of still healthy white matter. In the neck the sclerotic change may extend from the point of the anterior cornu in front almost to the posterior nerve-root behind. But in its passage down the cord it occupies a smaller and smaller space, both relatively and actually, and at the same time limits itself more and more to the neighbourhood of the posterior cornu and the nerve fibres springing from it. Thus in the middle of the dorsal region its anterior limit corresponds to a transverse line drawn through the commissure, while in the lumbar enlargement it occupies only the posterior fourth of the lateral column. (See fig. 99, A, p. 987.) Occasionally the fasciculus of Türck of the same side as the cerebral lesion shares in the morbid change. In total transverse lesions of the spinal cord similar degenerative changes take place in the lateral columns below the seat of disease. But in this case the degeneration involves both sides equally, and generally abuts on the pia mater.

Lateral sclerosis of idiopathic origin affects identically the same tracts, and, as in the last case, both sides of the cord are as a rule simultaneously implicated, and the lesion presents a symmetrical character; but it is said usually to have a wider lateral extent, and to reach not only the surface of the cord, but the grey matter of the posterior cornua. (See fig. 99, B, p. 987.)

It is an important fact that the morbid process occasionally extends horizontally beyond the lateral white columns, and that this extension is more common in the idiopathic disease than in that which is secondary. When this lateral extension takes place it is seldom, if ever, general; it comparatively rarely involves the sensory tracts of the grey matter of the cord, the posterior columns, or the posterior roots; but almost always it is the anterior cornua with their groups of large cells that suffer. The anatomical lesion, in fact, which constitutes the basis of the group of affections last considered, becomes superadded to the primary lesion of the lateral columns. This lateral extension, however, does not occur in all situations equally, nor does it take place here and there indifferently. It is almost invariably most advanced in the cervical portion of the cord, and diminishes gradually thence downwards. It comes on also, though at a comparatively late period of the disease, in the medulla oblongata, leading then to special implication of the nuclei of the spinal accessory, hypoglossal, vagus, and facial nerves. Both the naked eye and the microscopic characters of sclerosis have already been sufficiently considered. It need only be added that the sclerotic process in the anterior cornua, which is associated with lateral sclerosis, is undistinguishable from that which occurs primarily in them; and that it is followed sooner or later by the same secondary changes in the motor nerves and voluntary muscles that have already been described in connection with infantile paralysis.

*Symptoms and progress.*—The symptoms specially referrible to disease of the lateral columns are, gradually developing paralysis of the muscles with which the affected tracts are in relation, occasionally attended with tremors during the attempt to perform voluntary movements

and gradually increasing rigidity, often coming on in paroxysms, and easily induced by any kind of irritation. Further, the paralysed muscles are liable to paroxysms of convulsive trembling; and there is marked increase of the tendon reflexes, ankle-clonus, and other similar conditions. But the superficial reflex excitability, though at times increased, is generally unaltered or diminished; the electrical relations are for the most part unchanged; the muscles do not waste; and there is neither pain nor loss of sensation, nor want of control over the bladder and rectum. The above symptoms form an essential part of all the varieties of the disease now about to be described.

1. *Secondary lateral sclerosis (amyotrophie spinale deutéropathique).*—

a. The simplest forms of this affection are those which commonly supervene on so-called 'focal' lesions of the hemispheres of the brain, and on similar localised affections of the cord. In the former case, after hemorrhage or softening or other circumscribed lesions, in association with persisting paralysis, the muscles of the affected side, and mainly those of the limbs, tend to become rigid—the rigidity at first being occasional, but later more or less permanent, generally disappearing or diminishing during sleep, and varying in degree in different cases. The arm usually suffers most, and as a general rule is drawn to the side; the elbow is bent, the forearm partially pronated, and the wrist and fingers flexed. The leg more frequently escapes than the arm, and for the most part suffers less; it is generally extended, and the toes are pointed. The lower part of the face is occasionally involved, in which case the angle of the mouth becomes drawn to the paralysed side. The tendon reflexes are all increased; the superficial reflexes undergo diminution.

b. Many of the symptoms which become developed in the course of ordinary paraplegia, and form some of its most striking features, appear to be largely dependent on the secondary degeneration of the cord which always ensues. These are the clonic and tonic spasms, and the exaggerated tendon reflexes, which also constitute characteristic traits of the primary varieties of lateral sclerosis presently to be described; and need not therefore now be specially discussed.

c. But these secondary degenerations of the cord are not unfrequently complicated with other symptoms due either to lateral extension of disease in the brain or cord, as the case may be, or to the primary lesion to which the descending changes are secondary. The cases here referred to are for the most part cerebral.

In the case of adults in whom imperfect hemiplegia has resulted from cerebral mischief, there not unfrequently ensues (in association with chronic rigidity of the limbs) a condition to which the name of *post-hemiplegic chorea* has been given. This comes on at various times after the primary malady, and for the most part after amendment has taken place. The movements, which are generally something like those of chorea, may involve arm and leg and face, or arm and leg, or arm only; and under any circumstances are most marked in the arm. Sometimes they consist of merely slow irregular movements of the fingers (*athetosis*); sometimes

of movements, more or less violent and rapid, affecting chiefly the fingers, and in a diminishing ratio the wrist, the forearm, and the upper arm, the movements in some cases being so violent and uncontrollable that the patient is compelled to have his arm tied to his side, or otherwise restrained; sometimes the convulsions are distinctly choreiform. Hemi-anæsthesia is often associated with this condition.

When the affection shows itself in early childhood, it is usually the result of congenital disease of the brain, or of damage inflicted on the brain during birth or shortly after birth, or originates in attacks of convulsions occurring during the first few years of life. It may also be secondary to acute anterior poliomyelitis, affecting mainly the upper part of the cord. In such cases the limbs on the affected side remain more or less rigid; but atrophy (like that coming on after infantile paralysis, and involving the bones as well as the muscles) is apt to ensue; sometimes affecting the face, sometimes the arm, sometimes, but more rarely, the side generally. Moreover, epileptic attacks are liable to come on in early life and to continue, and more or less mental deficiency is generally present. Choreic movements, or movements like those of athetosis, are apt to be associated with the other symptoms. Sometimes the lesion producing degeneration is double; and in extreme cases of the kind we find, associated with cerebral symptoms (such as have been above described) and perhaps with atrophy of certain limbs, general clonic convulsions exactly resembling those of chorea, and characteristic spastic paralysis of arms and legs, but chiefly the latter, the patient walking with the limbs stiff and extended, the feet in the position of talipes equino-varus, the thighs strongly abducted, and the movements jerky or trembling. In these cases there can be no doubt that, whatever the primary lesion may have been, and whatever further changes may have taken place in the brain, there is extensive degeneration of the lateral columns, which in certain parts of the cord (and more particularly perhaps in the medulla and cervical region) has invaded the anterior cornua and thus led to the combination of the characteristic consequences of this condition with those due to simple lateral sclerosis.

2. *Idiopathic lateral sclerosis*.—There are good reasons for believing that the affections now about to be described are merely varieties of disseminated sclerosis. But, even if this be so, there is no doubt that many cases are met with to which the descriptions we are about to give apply, and which may be regarded, at any rate clinically, as cases of lateral sclerosis.

a. The commonest form of this affection (*spasmodic tabes dorsalis*) is met with chiefly in men, though it may also attack women and children. It comes on gradually (for the most part without premonitory symptoms) with weakness and sense of fatigue in one or both legs. This condition slowly increases on the patient, who finds, sooner or later, that his feet drag, that his gait becomes awkward, that he needs the assistance of a stick in walking, and that he is readily fatigued. But his health is good, he has no numbness or pain, and no affection of the bladder or rectum or

of the sexual functions. Neither is there any wasting of the muscles. There are no ataxic symptoms, and he can stand with his eyes closed. Gradually, as the disease progresses, the phenomena specially referrible to affections of the lateral columns supervene. Occasionally twitchings of the legs come on, mainly at night or when he is sitting down; or spasmodic stiffness of some moments' duration arises, particularly when his muscles are being exercised. At first these additional phenomena are so slight as scarcely to attract his attention; but, in association with advancing paresis, they gradually increase upon him, and at length constitute striking features in his disease. The legs become more and more liable to spasmodic contractions, which come on without obvious cause, and are readily excited by any form of stimulus; they become suddenly rigid, sometimes flexed, sometimes extended, and are apt to remain for some time in that condition. The spasms are chiefly liable to occur when he attempts to walk; and then especially cause powerful adduction (occasionally crossing) of the thighs, with more or less marked extension at the different joints. The extension at the ankle-joints imparts to the feet the attitude of talipes equino-varus. Associated with the spasms are more or less violent tremblings, developed mainly when the weight of the body is made to rest on the toes (and therefore of the same character as the ankle-clonus), which add to the patient's difficulty of walking, and give it a peculiar jerky character. When the paralysis is complete the rigidity becomes permanent, the legs being in some cases extended, in some flexed, and exceedingly difficult to bend or straighten. At this time (or even earlier) prolonged paroxysms of spasmodic trembling can often be readily induced in them.

The symptoms, however, do not remain limited to the lower extremities, but gradually mount upwards; and long before the affection of the legs has become extreme, the muscles of the back and abdomen get weak and rigid, and the patient consequently has difficulty in supporting himself in the upright or sitting posture, and in executing movements of the trunk. Later, probably, the arms become implicated in the same way; they get heavy, stiff, and weak; and finally rigidity and contraction occur. In an advanced stage the arms are pressed against the trunk, the forearms are bent and pronated, and the wrists and fingers are strongly flexed.

The development of the paralysis does not always accord with the above sketch, for occasionally it begins in the arms and travels downwards; and occasionally for a time it assumes a hemiplegic character. Further, it now and then affects a limb and remains limited to it. It is important to observe that during the whole course of the disease (unless complications should occur) there is no pain or loss of feeling, no paralytic affection of the emunctories, no tendency to bed-sores, no cerebral disorder; the tendon reflexes are notably exaggerated, while the superficial reflexes for the most part remain normal: and there is a little lowering of faradic and galvanic excitability, without qualitative change.

The course of the disease is almost always extremely slow; and months, even years, may elapse before its true nature is revealed; and

many years before it becomes generalised, and before even the patient altogether loses the power of locomotion. Absolute paralysis, indeed, with permanent stiffness of the muscles, only takes place at a very advanced stage, and may never be reached. Erb records a case or two of recovery from this disease; and there is no doubt that occasionally it becomes arrested in its course. But in the great majority of cases it is progressive, even though it does not necessarily shorten life. Death usually results from intercurrent disorders, or disorders independent of the primary disease; but it may be due to extension to the medulla oblongata or other parts of the cord, or to the supervention at a late stage of bed-sores, bladder trouble, and the like.

b. The form of idiopathic lateral sclerosis described by Charcot under the name of *sclérose latérale amyotrophique* is a complex affection of great gravity; in which, as a rule, sclerosis begins in the upper part of the cord, involving not only the lateral columns but the anterior horns; and in which there is a special tendency towards involvement of the motor ganglia of the medulla oblongata. It is said to occur chiefly in women. In most cases the disease comes on insidiously, without fever or premonitory symptoms other than perhaps some numbness or tingling in the limb over which paralysis impends. The arms are usually first implicated, first one probably, and the other after a short interval. They become enfeebled and more or less emaciated; the enfeeblement, however, precedes the emaciation, or goes along with it, and does not, as in wasting palsy, follow it. Moreover, in this affection, the paralysis and wasting attack all the muscles of the affected limbs simultaneously, instead of, as in the other case, creeping from muscle to muscle. Further, the shrinking muscles are liable, as are those of wasting palsy, to fibrillar vibrations, and retain like them their faradic contractility; and, moreover, so long as any voluntary motor power remains in them, their movements are generally attended with more or less violent trembling. But, in addition to the phenomena above enumerated, the emaciated and paralysed limbs soon become rigid and contracted, and, as a consequence of this contraction, deformed. Each arm is kept closely applied along the side of the body, and the shoulder resists when we attempt to abduct it; the forearm is semiflexed and pronated, and cannot be extended or supinated without the use of considerable force, and exciting pain; the hand is flexed on the forearm; and the fingers also are flexed. In the further progress of the case emaciation tends to become extreme; and at length with the atrophy of the muscles their capability of contracting under the stimulus of electricity may fail, and their rigidity and contraction may to some extent disappear. In some cases the muscles of the neck get rigid, like those of the arms, and the patient has pain and difficulty in moving his head.

The atrophy of the arms in this affection is far more rapid than in progressive muscular atrophy, mainly, no doubt, because all the muscles are involved at one and the same time; and at the end of four, five, or six months, or at the outside a year, the emaciation is as extreme as we observe it to be in cases of progressive muscular atrophy which have been in progress

for several years. From six months to a year or more after the commencement of the disease, the lower extremities generally first give signs of involvement. The patient complains of numbness, tingling, and loss of power in them; but in their case there is very seldom any atrophy, owing evidently to the fact that the motor nuclei of the dorsal and lumbar regions are scarcely ever involved. The paralysis of the legs, however, makes rapid progress; the patient soon cannot walk without being supported on either side; and before long all voluntary movement ceases in them. The paralytic phenomena presented by the legs correspond exactly with those occurring in the form of the affection previously described; excepting, as already stated, that some numbness is often present, and the progress of events is much accelerated. After a while, but this is a remote and comparatively rare event, the muscles of the legs undergo atrophy like those of the arms; and with the advance of this atrophy the rigidity gradually relaxes. There is no paralysis of bladder or rectum, or tendency to the formation of bed-sores.

While the legs are becoming paralytic, or it may be after arms and legs have lost all power of voluntary movement, another series of phenomena gradually supervenes, referrible to implication of the motor nuclei of the medulla oblongata. These are: paralysis of the lips and face; paralysis of the tongue; paralysis of the soft palate; and paralysis of the parts to which the vagus is distributed—a group of phenomena which will hereafter be considered as a distinct affection, under the name of ‘glosso-labio-laryngeal palsy.’

The prognosis of the disease, at all events when it presents distinctive characters, is exceedingly gloomy. Its various stages follow one another surely and rapidly, and death usually takes place within one, two, or three years from the commencement of paralytic symptoms. The contrast in this respect between this variety of lateral sclerosis and wasting palsy is very striking. Death is generally due to accidents connected with involvement of nerves of the medulla oblongata.

*Treatment*.—The treatment of lateral sclerosis, as far as we know, is the same as that of tabes dorsalis. We must attend to the general health, resort to galvanism, baths, friction, and such like measures, and obviate as far as possible the various discomforts and dangers to which the patient is exposed. For medicine, iodide of potassium, nitrate of silver, arsenic, iron, and vegetable tonics are probably the most suitable.

### F. *Tabes Dorsalis* (*Locomotor Ataxy*)

*Definition*.—By the above terms is understood a peculiar affection, characterised: anatomically by sclerosis of the posterior columns of the cord; clinically by loss of co-ordinating power in the lower extremities, gradually increasing in degree and extent, and generally sooner or later involving the upper extremities and other parts. Various nervous lesions, which need not now be specified, are frequently associated with the muscular inco-ordination.

*Causation.*—The causes of locomotor ataxy, like those of most other affections of which a sclerotic condition of the nervous centres forms the anatomical basis, are exceedingly obscure. The disease has been referred to sexual excesses, to syphilis, to exposure to cold and wet, and to over-exertion, injury, or shock. But little more can be said positively than that in many cases some one of these various conditions has preceded the occurrence of the nervous phenomena. In the greater number of cases, however, no cause whatever can be assigned. The disease is occasionally hereditary, or runs in families, and, further, seems not unfrequently to be associated in families with insanity, epilepsy, and other affections of the nervous system. It seldom occurs in women, and generally first makes its appearance between the ages of twenty and forty-five. It sometimes, however, comes on at an advanced period of life, and sometimes about the age of puberty.

*Morbid anatomy.*—The specific lesion of locomotor ataxy is sclerosis of the posterior columns of the cord: both columns, as a rule, being equally

FIG. 105. Diagram to show seat of lesions in tabes dorsalis. Area of disease represented by transverse shading.

A. Limited to posterior external columns; B. Including whole of posterior columns, and extending also to the lateral columns.

affected, and the morbid change usually being most advanced in the lower part and diminishing from below upwards. In many cases the posterior columns are involved in their whole horizontal extent. But it is shown by Charcot, that such an amount of disorganisation

is unnecessary for the production of the characteristic symptoms of the disease; that in some cases the posterior median columns, or fasciculi of Goll, remain perfectly healthy; and that, in fact, the tracts whose lesions induce ataxic symptoms are two narrow bands of white matter, lying one on each side, between the inner and posterior aspect of the posterior cornu and nerve-roots on the one hand, and the posterior median column on the other. The sclerotic change occurring in these parts calls for no specific naked-eye or microscopic description; the affected columns become indurated, grey, and translucent, in the early stage a little swollen, but at a later period notably diminished in bulk. The disease, however, rarely remains strictly limited to the tracts which are its primary seat; in a large number of cases (as has already been indicated) the posterior median columns become involved; and generally the internal radicular fibres of the posterior roots of the nerves, and more or less of the adjoining parts of the posterior cornua, get implicated to some extent. Occasionally, also, the disease invades the lateral columns, and occasionally even reaches the anterior cornua; not, however, Charcot thinks, by gradual involvement of all the intermediate tissue, but by extension along the internal radicular fasciculi.

*Symptoms and progress.*—The invasion of locomotor ataxy is sometimes quite sudden; in other words, impairment of co-ordinating power

is the first symptom to declare itself. In the great majority of cases, however, the specific characters of the disease are only revealed after the patient has suffered for an indefinite time, sometimes many years, from premonitory symptoms. These are very various, but many of them are full of significance, and most belong equally to the fully declared disease. The more important of them are as follows:—First, *Pains*. These are of various kinds and are referrible to different parts. The most common are momentary sharp shooting pains, following the course of certain nerves, for the most part connected with the trunk or lower extremities, but occasionally implicating the branches of the fifth pair, or the great occipital. An erythematous or vesicular eruption sometimes appears in the area of distribution of the affected nerves. Another variety of pain is of a boring or stabbing character, and is generally limited to certain definite regions in the neighbourhood of the joints or along the back; and its occurrence is usually associated with hyperæsthesia of the same parts. A further variety is of a constrictive character; it mostly affects the trunk, constituting the so-called ‘girdle pain,’ but may involve the limbs or any part of them. These various forms of pain are often associated. The last of them is more or less persistent. But the others occur in momentary twinges, and their continuance is usually effected by a more or less rapid succession of such twinges. Sometimes they come on at irregular and long intervals, and then not unfrequently continue by successive paroxysms for several hours or several days; sometimes they recur many times daily; sometimes they are constant, and wear the patient out by their unceasing severity. They are generally worse at night-time. *Pains referrible to the viscera* are also not unfrequent. Among them may be included pain in the bladder attended with the frequent desire to make water, pain in the urethra excited by the act of micturition, and pain in the rectum as if the bowel were being distended, associated with violent tenesmus. The most important and characteristic of them, however, are attacks of gastralgia (*crises gastriques*) of extreme intensity, usually attended with vomiting, faintness, deranged action of the heart, and an extreme sense of illness. These may continue for several days, or even weeks, at a time; separated from one another by intervals of entire freedom of variable duration. Occasionally the gastralgia is persistent, though liable to exacerbations. The pains in the stomach shoot to the back, about the abdomen, and in various other directions. Second, *Paralyses of motor and sensory nerves*. These are sometimes temporary, and apt to recur at intervals, sometimes permanent. Among the least common of them are hemiplegia, facial paralysis, difficulty of swallowing, and anæsthesia in the area of distribution of the fifth pair; among the most common, paralysis of the external rectus or of the other muscles of the eyeball, and ptosis. Third, *Affections of the eye and ear*. We have already referred to the fact that the patient may have an internal or external squint, or ptosis. It may be added that extreme contraction of the pupil is a marked feature of the disease; that the pupils are sometimes unequal; and that the contracted pupil is apt

to dilate under the influence of the attacks of pain to which the patient is subject. But besides these conditions, which are obvious to casual observers, there are others of yet greater significance and importance. The patient's eyesight in many cases becomes defective: he sees double; or his vision gets dim or indistinct, and he cannot distinguish small objects or the contours of objects so clearly as he formerly did; or his field of vision becomes contracted, limited perhaps to one side; or there is some failure in the power of distinguishing colours, he recognises yellow and blue, but fails to distinguish red and green, and the secondary tints in the production of which these colours are concerned; or these various conditions are associated in a greater or less degree. These affections of the eyesight tend to increase slowly, and at length culminate in absolute blindness. They are due to progressive grey atrophy of the optic discs, revealed ophthalmoscopically by chalkiness and opacity, with absence of the marginal rosiness of tint, and by inability to trace the trunk-vessels of the retinae as they sink into the substance of the optic nerves—they seem to terminate abruptly. The atrophy, according to Charcot, is due to a change occurring in the optic discs (identical with that which goes on in the posterior columns of the cord), and gradually extending backwards along the optic tracts, as far at least as the corpora geniculata. Further, in a large proportion of cases the pupils cease to act to the stimulus of light, while still varying in size with efforts at accommodation (the *Argyll-Robertson phenomenon*). Headache referred to the back of the head and forehead, and neuralgic pains in the course of the branches of the fifth pair, and in the eyeball, frequently attend the above visual lesions. Deafness in one or both ears is not uncommon. Fourth, *Affections of the joints*. These are of occasional occurrence; they are observed mainly in the knees and hips, sometimes in the shoulders. They consist in rapid effusion into the joints and tissues which surround them, taking place with little or no pain or fever, and usually followed at the end of some weeks or months by restoration to health. Occasionally they end in erosion of the ends of the bones, or disorganisation of the joints, followed after a time by dislocation. In association with joint-disease atrophy and brittleness of bones have often been observed; and there is some reason for believing that these constitute the primary affection. Fifth, in almost all cases, not only when the disease is fully developed, but at its very earliest stage, and even before its true nature has been revealed, there is a total absence of patellar and other tendon reflexes. It is curious, however, that there is no relation between the absence of this phenomenon and the condition of the superficial reflex excitability. The latter, although occasionally impaired or even exalted, remains for the most part normal. Lastly, among other occasional precursory symptoms may be enumerated: nocturnal incontinence of urine; spermatorrhœa, sometimes attended with erection and voluptuous sensations, sometimes occurring independently of erection or of orgasm; a peculiar aptitude for repeating the sexual act many times within a short period; loss of sexual power and desire; and a

permanent acceleration of pulse, attended, according to M. Eulenberg, with habitual dirotism.

The explanation of the phenomena just enumerated is for the most part obvious. They are dependent on the progress and distribution of the morbid process which is going on in the nervous centres, but which has not yet destroyed, sufficiently to cause obvious inco-ordination, those portions of the cord which minister to the co-ordinate actions of the lower extremities. Thus, the various forms of neuralgic pain and cutaneous eruption are due to implication of the intra-rhachidian portions of the sensory nerve-roots; the affections of the eyes and ears are referrible to involvement of the ophthalmic and auditory nerves, or their nuclei; and there are good grounds for believing that the lesions of the joints are the consequence of implication of the anterior cornua, and that various phenomena, such as those presented by the pupils and those connected with the action of the heart and character of the pulse, are of sympathetic origin.

The so-called 'premonitory' symptoms are in truth an integral part of the disease, and if recognised may be taken as sure evidence of the insidious progress of those central organic lesions which ultimately induce the proper ataxic phenomena. Some one or more of these premonitory symptoms may continue for years before the occurrence of obvious ataxia; the disease may even stop short with them; but in many cases those which first made their appearance undergo gradual aggravation, others become added to them, and presently the ataxic phenomena supervene and become mingled, as it were, with them. In other cases, again, want of co-ordination in the movements of the lower extremities is the very first indication of nervous disease, and various of the phenomena hitherto spoken of as prodromal appear as complications only during its later progress.

The earliest of the special phenomena of locomotor ataxy is the gradual supervention of a certain difficulty in walking, associated with numbness and tingling of the toes and feet, and occasionally with hyperidrosis of the same parts. The difficulty is peculiar in its character; it does not consist in any loss of muscular power or any inability to take long walks without discomfort or fatigue, but in a certain clumsiness or uncertainty which manifests itself especially when the patient first rises from his seat, or when he is endeavouring to avoid obstacles, or when he attempts to turn suddenly on his heels, or to go upstairs. It becomes especially obvious in the dusk; and, indeed, the very first indication of disease is sometimes the difficulty which the patient experiences in walking in the dark. Under all these circumstances, his movements become more or less tumultuous, and there is an obvious difficulty in the maintenance of his equilibrium. This difficulty becomes evident in the most marked manner, even in the very earliest stage of the disease, when the patient is made to stand blindfold with his feet together. At once he begins to totter and to sway, and, unless he opens his eyes or is supported by others, soon falls to the ground. With the progress of the disease the movements all become more tumultuous, and the difficulty of

progression increases proportionately ; the patient now perhaps experiences considerable difficulty in assuming the erect posture ; in endeavouring to attain it his legs jerk here and there, apparently urged by an uncontrollable impulse, and he has to resort to a stick, or the arm of his chair, or to a friendly hand to aid him in his efforts. When once he is on his legs, he pauses for a while to balance himself, and then starts off with his body bent forwards and his legs apart. Every movement of his legs is now tumultuous ; the leg with which he steps out is lifted from the ground and thrown forwards and upwards with needless suddenness and violence, and is then brought down with equally unnecessary force, and even when on the ground still presents a tendency to jerk, which may be continued even while the other leg is in its turn executing its series of awkward progressional movements. The patient continues to walk in this manner either without assistance, or with the aid of a stick or chair, or between a couple of friends, according to the stage which his loss of co-ordinating power has reached. But if he be able to walk alone or with a stick, his movements usually become a little less wild after he has taken a few steps ; and he may continue to walk, with excessive violence of movement, no doubt, and with short hurried steps and the body thrown forwards, but nevertheless with considerable power and efficiency. A patient in this state will sometimes walk ten, a dozen, or twenty miles at a stretch, with comparatively little fatigue ; but in some cases the mere violence of his muscular movements involves such rapid exhaustion of power that the sufferer can scarcely do more than walk across the room. A time, however, comes sooner or later in which his want of control over the movements of his lower extremities becomes so extreme that it is absolutely impossible for him to make a step or two consecutively or even to stand. His legs, when he attempts to use them, move, as Trousseau observes, like those of a puppet or marionette. Thenceforward he is confined to his chair or bed. It is a remarkable fact, for the due appreciation of which we are indebted to Duchenne, that the muscles of the affected limbs retain as a rule, their bulk, their tonicity, their electrical contractility, and their strength, little if at all impaired, not only so long as the patient can walk or stand, but long after his limbs have become absolutely helpless. And often, at a time when the patient cannot rise from his chair or stand, he can freely execute movements of extension and flexion as he sits or lies, and successfully resist all manual efforts on the part of his physician to extend or flex his legs. The numbness and tingling to which reference has already been made generally persist, and for the most part increase in degree and extent, and always from below upwards. There is sometimes total abolition of cutaneous sensibility in the feet, and there may be some impairment of it extending even to the abdomen. Occasionally it is absent. This impairment of sensibility gives to the patient the impression that his feet are swollen and soft, or that they are enveloped in some thick soft covering, and when he stands or walks that he treads on sponge or wool, or some other yielding and elastic material, or even that he treads on air. However great the loss of tactile sensibility.

that which takes cognisance of differences of temperature usually survives to the last.

The symptoms of ataxy do not generally remain limited to the lower extremities. In most cases, sooner or later, numbness, at first perhaps occasional, but after a while permanent, is complained of in the tips of one or two of the fingers—generally the little and ring fingers; and the numbness may remain thus limited, or may gradually involve more and more of the hand and arm, always, however, continuing most highly developed in the parts which were first attacked. In association with this, clumsiness in the movements of the fingers, and probably of the hands and arms, may be observed. The patient experiences considerable difficulty in performing all delicate manipulations; he cannot pick up a pin lying upon a hard smooth surface; he cannot button or unbutton his clothes or tie a bow, especially if he be unable to direct the operation with his eyes; in grasping a pen or any other similar object which is offered to him he first opens his hand wide and then closes it with violence upon it, entirely failing to execute those delicate combined movements which are necessary to the precision of his performance, and which impart such grace to the natural movements of the hand. The same clumsiness is observable in his efforts to transfer the object from one hand to the other, and, if it be a pen, in acquiring that hold of it which is proper for writing. Further (and this is a defect belonging equally to the lower extremities, but less readily recognised in their case), the patient is unable without the assistance of his eyes to judge of the position of his hands, or so to adjust the action of his muscles as to determine accurately the direction or extent of the movements of his arms. Hence, if his eyes be closed, he cannot if he wishes to clasp his hands bring them together with any certainty: they are brought towards one another at different elevations, or one in front of the other, and it is only after several failures have been made that they finally meet. Similarly, if he tries to touch his nose with his finger, he probably strikes his eye or his forehead or his mouth. The voluntary motions of the arms are occasionally effected by successions of jerky movements. But notwithstanding the widespread affection of his voluntary muscles, he probably during the whole duration of his illness retains perfect control over the rectum and bladder, and has no tendency to bed-sores.

Various other phenomena, due mostly to extension or multiplication of the nervous lesion, are apt to supervene in the course of the disease. In some cases the muscles of the trunk and of the head and neck become implicated in the same way as the muscles of the extremities, and the patient executes slight oscillatory movements when he sits up unsupported. In some cases difficulty of articulation comes on; the patient is slow, yet somewhat jerky and indistinct in utterance; he can pronounce every letter perfectly, but fails to pronounce them accurately in combination and slurs over his syllables. There is often, too, a manifest over-exertion of the muscles of the mouth and tongue in the effort to speak, and fatigue is soon experienced. In some cases if such phenomena have not appeared earlier

in the disease) paralysis of the third, fourth, sixth, portio dura, hypoglossal or vagus of one or other side, comes on; or double vision, impairment of vision, or amaurosis supervenes; or the patient grows absolutely deaf; or he becomes subject to the various forms of pain which have already been described; while, on the other hand, if these have previously existed, they may disappear. The patient may also suffer from perforating ulcer of the foot, or even (though much more rarely) of the hand. Further, he may be liable to severe and continuous aching pains in the forehead and back of the head, along the spine, and in the trunk and extremities, in connection with which, as with the earlier neuralgic pains, cutaneous eruptions may appear temporarily; or he may, late in the disease, suffer from retention or incontinence of urine, and equivalent conditions affecting the rectum; and generally he loses sooner or later all sexual desire and power. Occasionally, in the far-advanced stages of the disease, rigidity, contraction, and wasting of muscles come on—complications which are obviously due to the extension of disease from the posterior columns to the lateral columns and anterior cornua.

In most cases the cerebral functions are unaffected from first to last. But in some instances patients become low-spirited and incapable of application; in some, manifest symptoms of insanity arise; in some, general paralysis of the insane supervenes; and occasionally (as also in this last affection and in disseminated sclerosis) epileptiform or apoplectic attacks occur. For the most part these phenomena come on late. But they may appear at any period, and may even constitute a part of the prodromal stage.

Locomotor ataxy does not always involve the opposite limbs symmetrically; it often commences earlier in one leg than the other, and invades one arm in advance of its fellow; and in the subsequent progress of the disease the legs or arms may continue to be unequally affected. The course, too, of the disease is very various. Sometimes the symptoms arise and succeed one another so rapidly that the patient becomes bed-ridden at the end of a few months. But much more commonly the successive phenomena are slowly and irregularly evolved; periods of apparent amendment from time to time intervene; and ten, twenty, or thirty years may elapse before the disease attains its full development. It is more than doubtful if absolute restoration to health ever takes place when the clinical phenomena are so fully declared as to render diagnosis clear. It is not, however, doubtful that many persons do experience great amelioration of their symptoms, and that such amelioration is sometimes of long duration. Occasionally, indeed, the course of the disease appears to be permanently arrested. In the vast majority of cases, however, the progress of the patient, excepting for occasional interruptions, is uniformly from bad to worse, until death ends the scene. The causes of death are various. Generally it is due to some intercurrent malady; but it may be referrible to implication of the muscles of deglutition and respiration, to secondary bladder and renal mischief, or to the formation of bed-sores.

*Treatment.*—When temporary improvement has occurred under our own observation, it has always seemed due simply to avoidance of over-exertion, rest, protection from cold and wet and other such adverse influences, judicious dieting, and good hours—in fact, to careful attention to the general well-being of the bodily health. It is not clear that any remedy exerts any, even the slightest, direct influence over the course of the disease. Nitrate of silver has been strongly recommended, iodide of potassium has been employed, iron and other so-called nervine tonics are often called into requisition. For the relief of pain, sedatives, such as opium or belladonna, or local applications, such as counter-irritants, frictions, and galvanism, may prove serviceable; and indeed it may be said generally that all complications and all discomforts arising in the course of the disease should if possible be relieved. Bathing and shampooing seem sometimes to be beneficial. As regards electricity, Duchenne observes that faradism, and galvanism with intermittent current, are either of them often serviceable both in relieving pain and in restoring voluntary power to the affected muscles in the earliest stage of the disease. But, while not forbidding their employment at a later period, he is evidently not sanguine as to the results which are then likely to be obtained. This is in accordance with general experience. Galvanism is doubtless preferable to faradism. Stretching of nerves has been practised with reputed success; and more recently suspension.

#### G. Glosso-labio-laryngeal Palsy (*Bulbar Paralysis*)

*Definition.*—This name has been given by Duchenne to a paralytic disorder due to an affection of the medulla oblongata (whence also it has been termed *paralysie bulbaire*) involving mainly the portio-dura, hypoglossal and spinal accessory nerves, and revealing itself during life by paralysis of the lips, tongue, soft palate, and larynx.

*Causation.*—Its causes are as obscure as those of other affections of the same class. It has been referred to the effects of cold and moisture, and it has appeared to follow upon strong moral emotions. It has also been referred to syphilis. It seems to be a disease of adult life, and to affect women more largely than men.

*Morbid anatomy.*—The essential lesions of this disease are identical, so far as regards their nature, with those of locomotor ataxy, lateral sclerosis, and the like. They affect, however, a different region. Post-mortem examinations conducted on patients dead of this affection have revealed sclerosis, with more or less atrophy, of the roots of the spinal accessory, hypoglossal, and facial nerves, and sometimes similar changes in the roots of the vagi, in the motor roots of the fifth pair, and in the anterior roots of several of the upper cervical nerves; but they have also revealed (which is of still greater importance) that these changes in the nerves are secondary to pigmental atrophy of the large cells contained in the nerve-nuclei situated in the medulla oblongata, associated with more or less circumambient sclerosis. Certain phenomena in the clinical history of these cases, and the fact of the frequent supervention of the symptoms of

glosso-labio-laryngeal palsy in the course of lateral sclerosis, render it probable that the disease, when occurring in the uncomplicated form, is often due less to a primary lesion of the nerve-nuclei than to their secondary implication in the course of some sclerotic change occupying the anterior pyramids.

*Symptoms and progress.*—In most uncomplicated cases of glosso-labio-laryngeal palsy the symptoms of the disease come on gradually. The tongue usually suffers first. The patient experiences some difficulty in the articulation of words, especially of those which need the special employment of the tip of the tongue, and presently also more or less difficulty in mastication and deglutition; and he suffers from the accumulation of saliva in his mouth. The paralytic condition of the tongue gradually increases; he has difficulty in protruding it and in drawing it in again, and ere long it lies motionless or nearly so on the floor of the mouth, with its tip behind the anterior incisors and its edge pressed and indented against the arch of the lower teeth. It is sometimes reduced in size and wrinkled; sometimes it feels large to the patient, and either retains its normal dimensions or exceeds them. Whilst the lingual paralysis is in progress, the muscles of the soft palate and arch of the fauces become implicated, the patient's voice acquires a nasal quality, the difficulty of swallowing becomes aggravated, and his food is apt to pass into the posterior nares. The arches of the palate may occasionally be seen to be unequal, with the uvula pointing to one side; but it is remarkable that even when the paralysis, so far as deglutition and enunciation are concerned, is complete, the velum often can still be excited by local irritation to violent action. The lips also are early involved: the orbicularis becomes enfeebled, the lips get large, the lower one pendulous, and it is soon difficult or impossible for the patient to close his mouth, to prevent the flow of saliva from it, to utter the labial consonants, to whistle or blow out a candle, or to perform any function requiring the use of the lips. According to Duchenne, it often happens that the quadratus menti and triangularis oris of each side become implicated, so that the angles of the mouth cannot be drawn down and extended; but he says that the buccinators rarely suffer, and that the muscles of expression of the upper part of the face remain unaffected, and by their tonic contraction so act on the angles of the mouth as to cause the transverse elongation of the orifice, and at the same time so deepen and modify the direction of the naso-labial sulci as to impart to the patient's physiognomy the appearance of crying. Not unfrequently, when a patient in this condition is made to laugh or cry, his mouth becomes widely opened, and remains open until the upper lip is restored to its original position by hand. The muscles by which the upward and downward movements of the lower jaw are effected for the most part retain their normal force, so that the patient can bite powerfully up to the last. Nevertheless, difficulty of mastication, already extreme in consequence of the paralytic condition of the tongue, is enhanced by paralysis of the pterygoid muscles, which renders the movements necessary for trituration impossible. Sooner or

later the muscles of the pharynx, and even those of the larynx, share in the general paralytic affection, and hence the difficulty of deglutition becomes further aggravated.

In the later stages of the disease the patient ceases to utter any articulate sound, although a laryngeal grunt, indicative of the due action of the vocal cords, may attend each effort to speak. The saliva which is constantly dripping from his lips accumulates in his mouth, becomes sticky from long retention, and on opening his jaws hangs in ropes and festoons between the opposite surfaces. His food collects in the buccal pouches, or falls out through the open lips, and can only be made to reach the fauces either by throwing the head backwards or by pushing the food onwards with the fingers. The pharyngeal stage of deglutition is equally difficult. Pultaceous matters are swallowed best; but these have to be passed to the back of the mouth in small quantities and with great care; and even then constantly cause choking—either finding their way into the windpipe or into the nose, or being ejected by the spasmodic action of the pharyngeal muscles. The entrance of food into the larynx is due mainly to the failure of the tongue and epiglottis to descend over the superior laryngeal orifice during the act of swallowing; for it is only in rare cases that suppression of the laryngeal voice, indicative of paralysis of the laryngeal muscles, is observed.

Sooner or later, however, the pneumogastric and spinal accessory nerves become implicated, and then symptoms referrible to the respiratory and circulatory organs are superadded. Attacks of difficulty of breathing, not due to the entrance of food or saliva into the windpipe, are now of frequent occurrence. They come on by day or night, and are often provoked by exertion. Duchenne refers them to paralysis of the bronchial muscles. They are certainly not unfrequently due to paralytic affections of the muscles of the larynx, and more especially to paralysis of the abductors of the vocal cords. No doubt catarrhal affections of the bronchial tubes are now exceedingly apt to arise, and these, however slight they may be, greatly aggravate, if they do not induce, dyspnoeal attacks. Remarkable feebleness of circulation also supervenes at this period; and especially the patient is liable to syncope attacks, which sometimes accompany the fits of dyspnoea, and are attended with præcordial anxiety, fear of death, and extreme feebleness, irregularity, and generally quickening, of the pulse.

The phenomena above described are all unattended with febrile disturbance, loss of sensation, pain, giddiness, or any form of mental defect; the appetite continues good, the corporeal functions generally are well performed, and the system at large for the most part retains its powers, excepting in so far as they may become impaired by the starvation which the difficulty of swallowing gradually induces. Hence some patients who are far advanced in the disease will continue to go about the house and even to take long walks. In many cases, however, towards the close of life, they are confined to the chair or to bed.

The course of glosso-labio-laryngeal palsy is generally rapid, and its

end is invariably death, which may come on within six months of its onset, and is very seldom delayed beyond three years. The causes of death are : starvation from inability to take nourishment ; asphyxia, from the impaction of a lump of solid food at the back of the throat, or from the repeated entrance of portions of food or saliva into the larynx ; an attack of dyspnoea or syncope ; and lastly, pulmonary complications (bronchitis and the like) which are especially dangerous when involvement of the respiratory muscles renders the discharge of bronchial accumulation difficult or impossible.

Although glosso-labio-laryngeal palsy conforms in a large number of cases to the description which has just been given, it is not unfrequently a fragment, as it were, of some more widely diffused nervous disease. Thus, as is subsequently pointed out, it often forms one of the complications of disseminated sclerosis ; its supervention constitutes, almost without exception, the last stage of lateral sclerosis ; and, further, it is not uncommonly associated with progressive muscular atrophy, generally coming on late, but sometimes manifesting itself at an early period. The most important cases of the last group are those (and they are not rare) in which the respiratory muscles also waste. Again, it is important to recollect that groups of symptoms closely resembling those of glosso-labio-laryngeal palsy may be caused by effusion of blood into the pons or medulla oblongata, or by syphilitic or other disease of the same parts ; and may even arise in connection with the descending lesions which follow chronic forms of cerebral disease.

*Treatment.*—Nothing that we are acquainted with is capable of arresting the course of this formidable malady. In the early stages electricity may be applied to the enfeebled muscles, and possibly with slight temporary apparent benefit. In the later stages we must endeavour to relieve symptoms ; and it may then be of service to feed the patient either by the aid of the stomach-pump, or per anum.

#### H. *Ophthalmoplegia Interna and Externa*

*Definition.*—The above names have been applied by Mr. Hutchinson<sup>1</sup> to two groups of cases, the one of which is characterised by progressive and more or less symmetrical paralysis of the internal muscles of the eyes, the other by progressive and more or less symmetrical paralysis of the muscles which move the eyeballs and raise the eyelids. Cases of the latter affection had previously been described by Von Gräfe.

*Causation and morbid anatomy.*—The causes and morbid anatomy of these disorders have not been satisfactorily determined. They occur in both males and females, and in large proportion in early adult life. Mr. Hutchinson states that in most of his cases there was a history of syphilis, and is inclined to attribute the ophthalmoplegia to this affection. No post-mortem evidence, however, of the presence of gummata in any of them has yet been adduced ; and he acknowledges that antisiphilitic

<sup>1</sup> *Medico-Chirurgical Transactions*, vols. lxi. and lxii.

remedies have had but little influence over their course. Some of the recorded cases have no doubt been attended with other phenomena strongly pointing to the presence of cerebral tumours, which may of course have been syphilitic. But in many the ocular affection has been associated with symptoms pointing to the presence of more or less extensive sclerosis of other parts of the nerve-centres; and there is good reason, therefore, to believe that ophthalmoplegia is, in many instances at any rate, a consequence of chronic inflammatory or degenerative lesions, and has intimate relations with other such affections. Ophthalmoplegia externa is occasionally functional.

The two forms of ophthalmoplegia, though apt to occur independently of one another, are not unfrequently combined; and there is reason, therefore, to believe that the lesions producing them severally occupy neighbouring, though not identical, parts of the nervous system. Direct symmetrical implication of the nuclei of the third, fourth, and sixth pairs of nerves in degenerative or other processes might well explain their concurrence; it might even explain (supposing definite parts of the several nuclei to be concerned in movements of the eyeballs, and other definite parts to be concerned in movements of the intra-ocular muscles) the separate occurrence of each.<sup>1</sup> There is some reason, however, to suspect that the parts involved in these affections may be (at any rate in some cases), not so much the nerve-nuclei themselves, as certain higher centres, not far removed from them, which co-ordinate the several forms of binocular movements. It has been shown by Henson and Voelcker that in the hinder part of the floor of the third ventricle there are three such centres; of which the one in front controls the action of the ciliary muscles, and so regulates accommodation, while the middle one regulates contraction, and the posterior one dilatation, of the pupils. Again, it has been shown by Adamuk that irritation of certain spots in the corpora quadrigemina produces severally elevation and depression of the eyeballs, and conjugate movements to the right and left. Now, affection of the former groups of nuclei would readily explain the occurrence of symmetrical paralyses of the internal muscles of the eyes; affection of the latter group would readily explain symmetrical paralyses of the muscles of the eyeballs; and, from the near proximity of the two regions, extension of disease from one to the other might readily take place and the symptoms referrible to each thus become combined.

In the only case of Mr. Hutchinson's which proved fatal, the symptoms had been going on for years; and there were in combination, not only external and internal ophthalmoplegia, but blindness and other progressive symptoms pointing either to locomotor ataxy, to lateral sclerosis, or to progressive muscular atrophy; and Dr. Gowers, who examined the nervous organs post mortem, discovered atrophy and degeneration of the optic nerves, and of the third, fourth, and sixth pairs with their nuclei, resembling the lesions found in progressive muscular atrophy. In a case under

<sup>1</sup> See Discussion, and Dr. Sturge, *Ophthalmological Transactions*, vol. i.

Dr. Buzzard's<sup>1</sup> case in which the symptoms of tabes were present in an extreme degree, and in which also ophthalmoplegia externa and immobility of pupils were present, the lesions indicative of locomotor ataxy were found far advanced in the cord, the nuclei of the sixth pair of nerves were found degenerated, apparently secondarily to vascular disease; and in the course of the nerves through the medulla were detected obstructed vessels and miliary clots. The other ocular nerves were not examined.

*Symptoms and progress.*—1. *Ophthalmoplegia interna*, in its most extreme and typical condition, is characterised by the presence of absolute immobility of both irides, and of total loss of the power of visual adjustment. The pupils undergo no change under the influence of either light or accommodation; and sight, which has become adapted to distant vision only, is wholly incapable of adjustment for near objects. The disease is slow in progress, begins sometimes in one eye, sometimes in both, and always in the first instance with paralysis of the irides. At this stage the patient is probably unaware that anything is the matter with his eyes, for mere immobility of the pupils scarcely affects the general perfection of eyesight. The loss of power of accommodation also for the most part comes on gradually, and often in one eye before the other. But occasionally it is almost sudden in its incidence. The failure of vision for near objects, and its increasing suitability for distant objects only, naturally attract the notice of the patient, especially if he be young; and now probably for the first time he consults a medical man.

2. *Ophthalmoplegia externa* also occasionally occurs independently of all other ocular disease, and indeed of all other disease. In such a case the first specific incident is usually partial ptosis affecting either both eyelids at the same time, or one in rapid succession to the other. With ptosis there is usually associated paralysis of the superior recti; and then, gradually following, but in no special order, paralysis of corresponding ocular muscles, until at length the paralysis becomes more or less general and complete. In a typical and extreme, but uncomplicated, case we find: the upper eyelids drooping over the eyeballs, with little or no power of voluntary elevation—imparting a sleepy aspect to the patient; the eyes almost absolutely motionless and looking directly forwards, or haply presenting an internal or external squint; and more or less marked exophthalmos, due to the absence of tonic contractile power in the muscles of the eyeballs; but withal integrity of the retinae, mobility of the pupils, power of accommodation, and for objects lying in the line of vision perfect sight. The immobility of the eyes necessitates incessant bird-like movements of the head in exercising the function of sight. The paralysis, however, is rarely so complete as is represented in the above picture. In most cases there is still some slight mobility of one or both eyeballs; or the disease, though affecting both sides, is more advanced on one than on the other. The progress of these cases, like that of ophthalmoplegia interna, is generally slow, and often extends over many years. But in some cases it is rapid; and the paralysis may become extreme in

<sup>1</sup> Buzzard, *Diseases of the Nervous System*, 1882.

the course of a few months. Pains in the eyes and head are often complained of.

3. Not unfrequently, in both forms of ophthalmoplegia, the patient becomes blind, with white atrophy of the optic discs; and not unfrequently also, as we have already pointed out, both forms of the disease are combined in the same patient.

The association of ophthalmoplegia with other nervous phenomena is extremely interesting. And abundant clinical evidence has now accrued to show: not only that the symptoms of these affections are apt to follow on such diseases as locomotor ataxy, disseminated sclerosis, bulbar paralysis, lateral sclerosis, and progressive muscular atrophy; but that they may be among the earlier symptoms, possibly the first recognised symptoms, of these well-known diseases, and may foretell their coming on. Paralysis of the motor portion of the fifth, the portio dura, spinal accessory, and hypoglossal nerves may severally also become developed during the progress of ophthalmoplegia; and in a case under our own care hemianæsthesia, with colour-blindness of the corresponding eye, and loss of smell and taste on the same side, appeared in the course of the patient's illness.

*Treatment.*—Some of Mr. Hutchinson's cases, especially those of ophthalmoplegia interna, seem to have been benefited by antisymphilitic remedies, a point of some importance in connection with the frequent presence of a syphilitic history. For the most part, however, treatment has proved of little service: and the affection, even if it has not developed into something worse, has either remained stationary or undergone gradual aggravation.

### I. *Disseminated Sclerosis (Multiple Sclerosis)*

*Definition.*—'Sclérose en plaques disséminées' is the name which Charcot (to whom we are mainly indebted for its recognition and description) has given to the affection which we here term disseminated sclerosis. Dr. Moxon calls it insular sclerosis. It is characterised, post mortem, by the presence of a number of small roundish patches of sclerosis, scattered irregularly throughout the nervous centres; clinically, by a variety of symptoms, among the most characteristic of which are tremblings of the head, neck, trunk, and limbs, coming on only when the muscles are being exerted, difficulty of speech, oscillation of the eyeballs, gradually supervening paralysis with contraction, chiefly of the lower extremities, and some impairment of the mental functions.

*Causation.*—Disseminated sclerosis is mainly a disease of adult life, usually coming on between the ages of twenty and twenty-five, rarely after thirty, but sometimes at the period of puberty, and even in childhood. It is more common in women than in men. It has been attributed to the same causes as those to which other forms of sclerosis have been attributed—namely, moral influences and exposure to wet and cold. Its advent has sometimes been heralded by hysteria, neuralgia, or other nervous symptoms.

*Morbid anatomy.*—Sclerotic patches may appear in the cerebrum, cerebellum, pons, medulla and spinal cord, either collectively or separately; but generally are distributed in several of these organs at the same time. In the cerebrum they occupy mainly the neighbourhood of the ventricles, and are found, therefore, in the corpus callosum, septum lucidum, corpora striata and optic thalami; they occur also in the centrum ovale, but seldom in the grey matter of the convolutions. In the cerebellum, their almost exclusive seat is the corpus dentatum. As regards the pons and medulla oblongata, they may be either superficial or deep-seated. In the former they affect mainly the anterior and inferior aspect, extending thence to the cerebral peduncles and corpora albicantia; in the medulla, they occupy all parts indifferently, inclusive of the region forming the floor of the fourth ventricle. In the cord, as in the medulla, all parts are liable to be implicated. The cerebral and spinal nerves sometimes emerge, unaffected, from diseased tracts; in other cases they are studded with similar morbid patches or are involved generally. The cerebral nerves which chiefly thus suffer are the first, second, and fifth pairs. The patches of sclerosis vary in size, but are for the most part well defined, and of roundish form. They are dense, hard, slightly translucent, and of a greyish colour, closely resembling that of the healthy grey matter of the brain. They sometimes project a little above the general level, sometimes are depressed below it. Microscopically they present all the ordinary characters of sclerosis; and usually, according to Charcot, may be divided into three zones, of which the outermost represents the disease in its earliest phase, the innermost represents it in its most advanced condition. In the outermost zone, the neuroglia is increased in amount and its nuclei in number, and the nerve-tubules are diminished in diameter at the expense of the white substance of Schwann; in the next zone, the neuroglia has still further increased and has become distinctly fibrillated, the nerves (more widely separated than they were) have become yet more reduced in size, and the white substance has almost wholly disappeared, while the axis-cylinder has in many cases undergone enlargement; in the central area, the overgrown neuroglia reigns paramount, the nerve-cells and nerve-tubules have for the most part vanished, and those which still survive are far advanced in atrophy. It may be added: that the gradual disappearance of the white matter of Schwann involves the production of a large number of free oil-globules and granule-cells, which stud the outer two zones, and tend to accumulate within the lymphatic sheaths of the vessels; that the blood-vessels enlarge, and the nuclei in their walls increase in number; that the nerve-cells undergo pigmental atrophy, shrink, and finally disappear; and that corpora amylacea tend to develop in the course of the vessels.

*Symptoms and progress.*—The symptoms to which patches of sclerosis may give rise must depend partly on their size, partly on their situation, partly on their number. Thus it is obvious: that if a patch of sclerosis should interrupt the continuity of the posterior columns of the cord, symptoms like those of locomotor ataxy would be developed; that if it should

involve one of the lateral columns, the symptoms referrible to it would have some resemblance to those characteristic of lateral sclerosis; that if the anterior cornua should be implicated, more or less rapid wasting of certain muscles might be expected to follow; that if the medulla oblongata should be its seat, some of the symptoms of bulbar paralysis or of glosso-labio-laryngeal palsy would necessarily arise; and that, if seated in the cerebrum, hemiplegia, convulsions, impairment of intelligence, or other of the various consequences of brain-lesion would almost certainly follow. It is, further, obvious that if many sclerotic patches should be distributed throughout the nervous centres, the consequences due severally to them would blend, as it were, into a common whole, producing collective symptoms of more or less complexity.

It is, nevertheless, a fact that a large number of cases of disseminated sclerosis, in which the nervous centres are generally implicated, are attended with groups of symptoms which collectively afford almost positive proof of the nature of the malady which is in progress. We will consider the more important of these symptoms successively.

1. *Rhythmical tremors*.—These constitute one of the most distinctive features of the disease. They are absent when the patient is asleep, they are absent also when he lies at rest, with his limbs and head supported; but they come on whenever he makes any muscular effort, and become more and more pronounced the greater and more sustained that effort is. When he raises his hand from the bed-clothes, convulsive movements seize his fingers, his hand, and his arm; if he attempt to raise his hand to his lips, the tremulous movements increase; and if, further, the muscular effort be rendered greater by his having to lift some heavy body, or something which requires care and precision in handling, as, for instance, a glass of water, they are apt to become exceedingly tumultuous, and to increase in tumultuousness as the task set him approaches completion. Occasionally they are induced when the arm is apparently at rest by the nervous efforts of the patient to keep it still. If he sit up unsupported, similar movements affect his trunk and his head and neck. If he endeavour to stand or to walk, they become universal, and the legs, arms, trunk, and head are all violently agitated. It is not pretended that these tremulous movements are present in all cases of disseminated sclerosis; but they are present in the great majority of cases. Nor must it be assumed that, when present, they are always of general distribution; they may (for a time at least) be limited to one arm, or to both arms, or when present in both may affect them unequally; or the legs may chiefly suffer. Neither must it be supposed that they are present during the whole course of the malady. Rhythmical trembling is rarely one of the earliest symptoms of the disease; but it usually comes on before long, and then invades the various parts slowly and irregularly; and it disappears as the patient becomes more and more enfeebled, and especially when paralysis supervenes. The movements are peculiar; they are rhythmical, and yet there is some degree of irregularity both in the extent of the successive vibrations and in the intervals which separate them. They have some resem-

blance to those of paralysis agitans ; but in the latter the vibrations are more rapid and more regular, moreover they occur when the patient is at rest, and seldom, if ever, directly implicate the head and neck. They have a greater resemblance still to those of chorea, but they are less wanton, less violent, and altogether more rhythmical than these ; and further, the vibrations in sclerosis for the most part take the direction of the general movement of the limb or part which is engaged in movement. It must not, however, be forgotten that tremulous movements, undistinguishable from those of sclerosis, may attend various other affections, and especially chronic mercurial poisoning, chronic cervical meningitis, and sclerosis of the lateral columns.

2. *Affections of the eyes.*—Double vision is a not uncommon symptom of the earlier stages of sclerosis, as it also is of locomotor ataxy, but is for the most part transitory and unimportant. Indistinctness of vision is a much more frequent phenomenon, and is generally permanent, but rarely ends in blindness. It is often present when no signs whatever of disease can be detected with the ophthalmoscope. But sometimes atrophy of the optic disc is present, which becomes complete in cases of total blindness. Nystagmus is a symptom of considerable importance, and is present in about half the total number of cases ; it consists in consensual small oscillations of the eyeballs, which in slightly advanced cases may be apparent only at the moment when the patient endeavours to fix his glance upon some fresh object, or looks out of the corners of his eyes ; but they are generally constant, although aggravated by voluntary movements of the eyeballs. They cease when the patient is asleep, or when his eyes are shut in repose. Nystagmus is rarely present in locomotor ataxy.

3. *Defect of speech.*—This is nearly constant. In well-marked cases the utterance is slow and drawling. The words (to use Charcot's expression) are 'scanned,' as it were, there is a pause after each syllable, and the syllables themselves are slowly evolved. Moreover, the voice is weak and monotonous, and only two or three words probably are uttered on each breath, owing apparently to rapid loss of breath by expiration during the inter-syllabic pauses. Also the words are often imperfectly pronounced, certain letters or difficult combinations of letters being slurred, and sometimes to such a degree that speech becomes unintelligible. Further, the lips and tongue are often tremulous : the lips tremble previous to the utterance of articulate sounds, and during the course of utterance ; and the tongue when it is protruded is in constant fibrillar movement. This tremulousness of the organs of speech adds to the difficulty of articulation, and imparts to it a peculiar tremulousness or uncertainty. A very similar defect of speech is apt to accompany locomotor ataxy, but in that case the tremulousness of the lips and tongue is absent, and (at least according to our observation) the muscular efforts to utter articulate sounds are unnecessarily violent.

4. *Vertigo* is an early symptom in about three-fourths of the total number of cases. It is mostly gyratory, and generally comes on in paroxysms of short duration, but is sometimes almost continuous. It often

interferes seriously with locomotion. The presence of nystagmus is also a cause of vertiginous sensation, the oscillations which take place in the eye-balls being referred by the patient to the objects which are figured on his retinae. Vertigo is not common either in tabes or in paralysis agitans.

5. *Paresis* of the limbs, and more especially of the lower extremities, comes on at an early stage of the disease. It generally begins in one leg. This feels weak and heavy, and drags in walking, but there are no movements indicative of inco-ordination. Soon the other leg becomes affected; but even then (so different from what occurs in tabic patients) so long as he has sufficient strength to stand he is capable of maintaining his equilibrium even when his eyes are shut. The weakness subsequently extends to the arms. This enfeeblement of the limbs gradually increases until it culminates in absolute motor paralysis; the convulsive oscillations of the earlier period undergoing proportionate diminution until they finally cease. The paralysis which commences in the lower limbs becomes as a rule complete in them while the arms are yet comparatively little involved. The patient not unfrequently complains of some degree of tingling and numbness, but there is rarely if ever any obvious impairment of cutaneous sensibility. Moreover, the muscular sense remains unaffected, so that he recognises exactly the position of objects and the amount of force necessary to accomplish various voluntary movements. There is no paralysis of the bladder or rectum; the affected muscles retain their form, bulk, and tonicity; and reflex and electrical contractility are for the most part unimpaired; but sometimes they are diminished. Frequently, on the other hand, and especially in those cases in which the affection of the lower extremities is of a paraplegic character, both ordinary reflex irritability and patellar reflex with other tendon reflexes of the lower extremities are greatly exaggerated. The paretic condition of the limbs is liable to remissions.

6. *Contraction of limbs*.—At some period or other in the course of the paretic symptoms, the lower extremities, either spontaneously or under excitement, become suddenly stiffened in extension, and pressed one against the other. These attacks may last some hours, or even some days, and are at first separated from one another by comparatively long intervals. But by degrees the intervals shorten, and, at length ceasing, the rigidity of the muscles becomes permanent. At this period the thighs are extended on the trunk, the legs on the thighs, the feet on the legs, and the members lie in close apposition, and cannot be separated. Sometimes the flexors overcome the extensors, and the limbs are flexed at all the joints. Occasionally, but at a later period, the arms become rigid and pressed against the sides of the body. At this time violent tremblings, lasting for a few minutes or even longer, are apt to arise in the stiffened limbs. These seem sometimes to come on spontaneously; but they may be excited by exposure to cold, or by pricking, tickling, electricity, or other forms of irritation; and they may extend from the limb in which they were first induced to the opposite limb, and even cause general trembling of the body. They may be at once stopped, according to Brown-Séquard, by forcibly flexing the great toe. This stiffening of the limbs

may be developed while their movements are still in some degree under the control of the patient, and does not therefore necessarily incapacitate him from walking with assistance.

7. *Expression and mental condition.*—During the course of the disease a marked change in the expression is apt to come on. The patient's glance is vague and uncertain, his lips pendulous and apart, his general aspect sad, weak, or fatuous. At the same time there is some change in his mental condition; the memory fails, the conceptions are slow, and the intellectual and affective faculties generally impaired. He is stupidly indifferent to all that goes on about him, and is apt to laugh or cry without occasion. Sometimes he becomes maniacal or demented. Sometimes the symptoms of disseminated sclerosis are associated with those of general paralysis of the insane.

One or more of the symptoms which have just been enumerated may fail in a greater or less degree in certain cases. But, on the other hand, additional phenomena are not unfrequently superadded. We have already suggested as possible complications certain phenomena which actually do not unfrequently present themselves in the course of the disease:—namely, inco-ordination of the movements of the lower extremities, and even of the hands and arms; wasting of certain of the voluntary muscles; and difficulties of deglutition, respiration, and circulation, indicative of involvement of the medulla oblongata. But, further, apoplectiform attacks are not unfrequent. These may come on without warning, or may be preceded by rapid failure of the mental faculties. They recur as a rule several times at irregular and long intervals. They are often attended with convulsions, which are usually unilateral, or with hemiplegia, associated sometimes with flaccidity, sometimes with rigidity of the paralysed muscles. In these attacks the pulse becomes greatly accelerated, and the temperature of the internal parts rises rapidly, so that probably in the course of the first few hours it mounts to  $102^{\circ}$ , and within twenty-four hour to as much as  $104^{\circ}$ . If the case is about to prove fatal, the temperature may reach  $108^{\circ}$  or  $109^{\circ}$ . In these cases bed-sores also are apt to form with great rapidity upon the sacral region. These apoplectiform attacks (which are not peculiar to disseminated sclerosis, but occur equally in cases of general paralysis and tumours of the brain, and in cases in which embolic softenings or apoplectic effusions have left chronic lesions behind them) are generally distinguishable from those due to hemorrhage by the fact of this sudden and rapid rise of temperature.

Charcot divides the clinical history of cases of disseminated sclerosis into three periods. The first extends from the first appearance of symptoms down to the supervention of rigidity of the limbs. The second includes all that time subsequent to the first appearance of rigidity during which the patient's symptoms undergo gradual aggravation, but during which the organic functions as yet maintain their integrity. The third commences with the failure of the nutritive functions.

*First period.*—The mode of invasion is various. Sometimes the dis-

ease commences with symptoms referrible to the brain, such as vertigo, or diplopia, soon followed by embarrassment of speech and nystagmus. More commonly the first symptoms are spinal, especially weakness of the lower extremities, which may continue for months or even for years before it becomes complicated with other phenomena. This weakness is liable to remissions, and is usually unattended with pain, loss or impairment of sensation, or difficulty of micturition or defæcation. It presents nothing distinctive. Rarely the disease commences with symptoms like those which usher in locomotor ataxy. The early progress of the disease is usually slow, but now and then the symptoms appear and follow one another with great rapidity. The contraction of the limbs, the supervention of which terminates this stage, does not usually show itself till after the lapse of two, four, or even six years.

*Second period.*—This is usually of long duration. During it all the characteristic symptoms of the disease are present and undergo gradual aggravation, until the patient becomes utterly helpless and confined to his chamber or his bed.

The *third period* comes on with progressive weakening of the organic functions. At the same time some of the symptoms proper to the disease come into special relief. Intelligence fails; the patient becomes, perhaps, fatuous; the sphincters cease to act, and the evacuations are all passed unconsciously; the bladder inflames; bed-sores form; and appetite for food declines. At this time, also, various intercurrent maladies are apt to come on, such as pneumonia, dysentery or diarrhœa, or difficulty of deglutition with other signs of involvement of the medulla oblongata.

The duration of the cerebro-spinal form of the disease usually varies between six and ten years; but, if the cord only be affected, life may be prolonged for twenty years or more. The causes of death are numerous. Among the more important may be enumerated: apoplectic attacks, the consequences of affection of the medulla, pneumonia and other intercurrent disorders, inflammation of the bladder, bed-sores, and debility from failure of the nutritive powers.

*Treatment.*—This appears always to have failed. Charcot observes that both strychnia and nitrate of silver have served for a time to check the trembling of the muscles, but have had no permanent good effect. Arsenic, belladonna, ergot of rye, and bromide of potassium have all been used at various times, but without obvious beneficial results. Little that is favourable can be said even of hydropathic treatment, or faradism, or the continuous current.

### *J. Friedreich's disease (Hereditary Tabes Dorsalis)*

*Definition.*—The affection to which this name is now commonly applied is a form of tabes dorsalis coming on in early life, in which symptoms of tabes and symptoms of disseminated sclerosis are associated.

*Causation.*—The causes of Friedreich's disease, as of other system diseases of the cord, are very obscure. In most recorded cases no sufficient cause was discovered. In a considerable minority, however, the

symptoms seemed to follow upon some febrile disorder, or specific febrile disease, such as small-pox or scarlet fever. It is remarkable that isolated cases are rare, and that, in large proportion, several children of a family suffer.

*Morbid anatomy.*—The lesions in the nervous system, found after death, are little if at all different from those occurring in locomotor ataxy. In all cases which have been examined, the most striking phenomenon has been sclerosis of the posterior columns of the cord, most extensive and most advanced in the lumbar region and diminishing upwards. But in addition sclerotic changes have in most instances been found extending into other regions, into the lateral or anterior columns, the grey matter, the medulla oblongata, or certain nerve-trunks.

*Symptoms and progress.*—The disease affects both males and females, and generally shows itself between the ages of five and sixteen. The first symptom usually noticed is a difficulty in walking, like that characteristic of tabes; with which is associated abolition of the tendon reflexes. As the disease progresses clumsiness in the use of the hands, as is often observed in tabes, generally comes on; and for the most part, though in varying order and at uncertain intervals, nystagmus, scanning or divided or drawling utterance, and tremors of the arms, head and neck, and trunk. It is curious, however, that numbness or loss of feeling, which is so constant in tabes, is either wholly absent in Friedreich's disease or slight, and then usually of late development; that although rheumatoid pains in the legs are not uncommon, lightning pains are rarely present, or are of brief duration; that the 'crises' of tabes seldom if ever occur; that, excepting nystagmus, no affection of the eyes has been observed; and that there seems no liability to affection of the joints. A characteristic feature of the disease is the gradual supervention of lateral, antero-posterior or oblique curvature of the spine, not unfrequently associated with talipes equinus or equino-varus. The mental condition remains unimpaired. Friedreich's disease is progressive, but of long duration; it may continue for thirty years or more. So far as is known it is incurable.

---

## VI. MULTIPLE NEURITIS.

*Definition.*—An inflammatory affection of the sensory and motor nerves, mainly those of the extremities, generally of symmetrical distribution, and causing sensory symptoms or motor paralysis with tendency to rapid wasting of the paralysed muscles.

Until recently the symptoms now generally referred to primary inflammation of the nerves were (notwithstanding that in fatal cases the cord was almost always found healthy) attributed to obscure disease of this centre. There is little doubt that Duchenne's 'subacute anterior general spinal paralysis,' or, as it has been subsequently named, 'subacute anterior polio-myelitis,' and so called 'alcoholic paralysis,' together with certain other affections characterised by more or less widely and symmetrically

distributed paralysis, which have been looked upon as affections originating in the spinal cord, are really due to disease of the peripheral nervous system.

*Causation.*—The causes of multiple neuritis appear to be various, and are certainly obscure. Exposure to wet and cold, overwork and privation, are doubtless responsible for many cases. Occasionally the neuritis follows on severe inflammatory disorders, such as quinsy, or certain of the acute specific fevers, as enteric fever, or supervenes in the course of chronic wasting diseases. Its most potent cause, however, would seem to be chronic alcoholism. At any rate the occurrence of multiple neuritis among persons who have been long addicted to excessive alcoholic indulgence is relatively very frequent. In the case of alcoholics there is reason to believe that the determining cause is not unfrequently some one of the other influences previously enumerated. It is a curious fact, of which as yet no sufficient explanation has been given, that the mortality among patients suffering from multiple neuritis is largely due to pulmonary tubercle. Multiple neuritis is a disease of adult life, and its alcoholic variety appears to be more common in women than in men.

*Morbid anatomy.*—The affection of the nerves in multiple neuritis differs in no respect either from that in which single nerves are inflamed, or from that of the white matter of the cord in the different system myelitic diseases. Three varieties of neuritis have been described: first, that in which the perineurium is primarily and chiefly affected; second, that in which the inflammation is interstitial; and third, that in which the disease appears to be parenchymatous, or to take its origin in the axis-cylinders of the nerves. In the former cases the nerves, at the seat of disease, become swollen and congested, inflammatory exudation takes place into the connective tissue surrounding and permeating them, and the nerve-fibres sooner or later undergo degenerative changes, beginning with the breaking-down and removal of the myeline sheaths, and going on to the degeneration and destruction of the axis-cylinders. In the last case the first visible evidences of disease are the degenerative changes which occur in the nerve-fibres; but secondary inflammation of the interstitial connective tissue soon ensues, and the morbid appearances before long are scarcely distinguishable from those presented in cases of neuritis beginning in the connective tissue.

In multiple neuritis the inflammation may affect any nerve and any part or length of a nerve; but the nerves of the limbs are chiefly liable to suffer, and for the most part the trunks and the branches down to those of medium size. The inflammation occasionally ascends from its seat of origin, but if it reaches the cord seldom if ever implicates the anterior roots. Much more frequently it spreads in the peripheral direction, and thus may even involve the terminations of the nerves in the muscular fibres. The changes in the smaller nerves are for the most part degenerative only, and are probably therefore in large proportion secondary. Occasionally contemporaneous sclerotic changes in the cord are found associated with the peripheral lesions.

The wasted muscles in this affection present the characters usually

observed in muscles in other forms of atrophic paralysis. They are paler than natural, their fibres are shrunken, more or less granular degeneration is not unfrequently found, and there may be some inflammatory or irritative overgrowth of the tissues which support them.

*Symptoms and progress.*—The symptoms of multiple neuritis comprise pain and tenderness in the course of the affected nerves, pain, hyperæsthesia, tingling or numbness of the *area* to which the affected sensory nerves are distributed, loss of power and limpness in the implicated muscles with rapid wasting, abolition of the superficial and tendon reflexes and development of the reactions of degeneration, and much tenderness and irritability of the muscular tissue. The sensory and paralytic symptoms are usually limited to the upper and lower extremities, and as a general rule are more pronounced at their distal than at their proximal ends. But the muscles of other parts occasionally suffer, namely, those of the trunk, the diaphragm, or the muscles of the larynx, throat, tongue, face, or eyeballs; and neuralgia, tingling, or loss of feeling may involve *area*, for the most part symmetrical, of the head and neck or trunk. There is seldom if ever any affection of the bladder or rectum; nor is it common to meet with nutritive lesions of the skin. The disease is generally acute or subacute in its onset, and slow in its progress; and, excepting in those cases in which the respiratory or laryngeal muscles are involved, for the most part ends sooner or later in more or less complete recovery. The symptoms and progress of the disease vary in different cases; and it is noteworthy that in slight cases where the lower extremities are involved, and especially in those among them in which the sensory nerves are alone or chiefly implicated, the patient's symptoms present a strong resemblance to those of *tabes dorsalis*. There are several varieties of multiple neuritis to which separate consideration may be given.

1. *Alcoholic paralysis, or multiple neuritis in persons of intemperate habits.*—This form of the disease sometimes comes on without any obvious determining cause; but sometimes first shows itself either while the patient is suffering from other consequences of alcoholic excess, or during an attack of some accidental febrile disorder. The patient probably complains first of tingling in the fingers and toes, or hands and feet; followed soon, or attended from the beginning, by gradually increasing loss of voluntary power in the limbs. The paralytic symptoms may come on simultaneously in all the extremities; or they may begin either in the arms or in the legs; and although they tend to be of symmetrical distribution, they are not unfrequently more pronounced on one side than the other. The symptoms usually progress rapidly, so that at the end of two or three weeks there may be a wide extent of numbness or tingling, and arms and legs may be absolutely powerless; and in the course of a month or two the limbs, and more especially the muscles of the legs and feet, forearms and hands, may have wasted to the last degree. In such cases the wrists are apt to drop, as in lead-palsy, and the hands and fingers to acquire a claw-like character, the distal joints of the fingers usually being more or less flexed, and the thumb lying in the same plane as the other

digits; moreover, the feet drop and become extended at the ankle, and the toes flexed into the sole. For a period, ranging from a few weeks to a few months, during which the disease is in progress, the muscles (especially those of the legs and forearms) are exceedingly tender, contract irritably when struck sharply, and not unfrequently the patient complains of tenderness in the course of the nerves, of neuralgic pains in the limbs, of pain and tenderness in the hands and feet, and probably still of more or less numbness in the same parts. It is generally during the earlier period of the disease that other paralyses, such as have been previously enumerated, come on. After a while the symptoms for the most part cease to progress, and then slow amendment follows. As a general rule the paralyses which were latest in development disappear soonest, and the muscles of the shoulders and upper arms, buttocks and thighs, show signs of recovery before those of the forearms and legs, hands and feet; the tenderness and irritability of the muscles subside; and the evidences of affection of the sensory nerves disappear. The muscles not unfrequently continue to waste even while they are manifestly regaining power. Alcoholic paralysis varies, of course, in its severity and extent. It may be general but slight, and unattended by obvious tenderness of nerves or muscles, or by any other sensory impairment than slight tingling in the fingers or toes. It may be limited to the upper or lower extremities, or, according to the description given, it may be not only of wide distribution, but absolute. The result varies. The majority of cases, whether they be slight or severe, get well sooner or later; though recovery in severe cases may be delayed for many months. In some instances the hands or feet, or both, remain permanently crippled. Occasionally death ensues, and may be due either to implication of the respiratory muscles, or to the effects of other coincident alcoholic disorders, or to tuberculosis or some other intercurrent disease.

2. *Idiopathic multiple neuritis*.—We assign this term, for convenience, to those cases which cannot be attributed to alcohol, and for which no specific cause can be assigned. On the whole the description given of alcoholic cases applies to these. The symptoms come on sometimes rapidly, sometimes slowly; they may be of wide distribution or limited to the upper or lower extremities; they may be slight in degree or the paralysis may be profound. In some instances recovery is rapid, in some it is long delayed. The symptoms and progress of the affection may, indeed, correspond accurately with those presented by the most aggravated examples of the alcoholic form. But, according to our own experience, numbness, at any rate extensive numbness, is less frequent; and in a very large proportion of the cases pain and tenderness in the nerves, muscles, and other tissues are conspicuously absent. Moreover, although the muscles as a rule waste, and sometimes waste to an extreme degree, in some cases they present scarcely any change of bulk from first to last. Again relapses are, we think, more common in this than in alcoholic paralysis; and thus the patient, though recovering ultimately, may remain paralysed off and on for several years.

3. *Kakké*, or *Beri-beri*, a specific febrile disease of Japan and some parts of the coast of Asia, is attended with multiple neuritis involving mainly the nerves of the lower extremities, and with some similar inflammatory affection of the cord. The symptoms referrible to the nervous disorder correspond in the main with those of alcoholic paralysis affecting the same parts.

4. *Diphtheritic paralysis*, which has been described earlier in this volume, has some claims to be regarded as due to an inflammatory condition of the nerves. Tenderness of muscles, and along nerve-trunks, has no doubt been observed in some cases. But such symptoms are certainly not always present. Moreover, there is a symmetry in the distribution of anæsthesia not unfrequently observed along the median line of the body, at the tip of the nose or tongue, about the chin, penis, or scrotum, or in other similarly circumstanced regions, that is more suggestive of central than of peripheral disease; there is usually at the beginning of paraplegic symptoms an exaggeration of the tendon reflexes such as is known to result from local affection of the cord, above the origin of the nerves to the lower extremities, and is hardly compatible with the presence of disease in the nerves themselves; and, lastly, although lesions have been discovered in the nerves in cases which have proved fatal, lesions have also been discovered in the cord. We incline to the belief that the affection causing nervous symptoms in diphtheria involves both the central and the peripheral nervous mechanism.

5. In some of the system-diseases of the spinal cord, affection of the peripheral nerves is apt to be associated with the central lesions. This is notably the case with *tabes dorsalis*. It occurs also, we believe, occasionally in infantile paralysis.

*Treatment.*—The treatment of multiple neuritis consists mainly in absolute rest, improvement or maintenance of the general health by food and tonics, and curing or obviating the conditions which appear to have induced it. It is obvious, therefore, that in all cases the habits of the patient should be carefully investigated, and that if there has been intemperance in drink this should be at once checked. Local treatment for the alleviation of pain is sometimes needed, and poultices, warm water dressings, sedative applications or injections, or counter-irritants may be of service. Again, local treatment is probably always called for sooner or later in relief of the affected muscles. In the beginning gentle frictions may be employed; and later, when the tenderness of muscles and nerves has disappeared, shampooing or massage, with passive movement of the joints, and the periodical use of galvanism are indicated. In order to overcome the deformity of feet, or hands, or other parts, due to contracture of muscles or to adhesions in or about the joints, mechanical treatment may be requisite. For internal administration, opium and *cannabis indica* are serviceable in relieving the neuralgic pains of the earlier stages of the disease; and iodide of potassium and mercury have been recommended for general use; but on the whole (unless there be proved syphilitic taint) we prefer quinine, iron, or other tonics.

VII. PARALYSIS AGITANS (*Shaking Palsy*)

*Definition.*—This is a disorder mainly of advanced life and of chronic progress, characterised especially by trembling of the limbs arising independently of voluntary movements, and for the most part sparing the head and neck. The patient in an advanced stage, without vertigo, is unable to maintain his equilibrium when walking.

*Causation.*—The causes of paralysis agitans are various. It would seem to be not unfrequently brought on more or less suddenly by violent emotion, such as terror, grief, rage, and the like. It is often referred, and probably with truth, to long-continued exposure to cold and wet. And it is asserted that it is occasionally traceable to wounds or bruises involving peripheral nerves; in favour of which statement is the fact that severe neuralgic pains referrible to such injuries have been succeeded by trembling of the parts involved, and subsequently by the general phenomena of paralysis agitans. There is little proof that the disease is hereditary. Neither does it belong to one sex more than the other. It is for the most part a malady of advanced life, usually first making its appearance after the age of forty. It may, however, occur at an earlier period, and cases are on record in which it commenced at twenty or even sixteen.

*Morbid anatomy.*—Of the condition of the nervous system in this affection nothing definite is known. Previously to Charcot's investigations paralysis agitans and disseminated sclerosis were usually confounded with one another, and the lesions of the latter disease were consequently regarded as having an important connection with the clinical phenomena of the malady now under consideration. In cases, however, of true paralysis agitans no constant lesions, sufficient at all events to explain the peculiarities of its symptoms, have yet been discovered. In some recent examinations of Charcot's there were found obliteration of the central canal of the cord by increase of its epithelial lining, overgrowth of the nuclei which surround the ependyma, and marked pigmentation of the nerve-cells, chiefly those of Clarke's posterior vesicular columns. It must be observed, however, that post-mortem examinations in cases of this disease are almost necessarily made on persons far advanced in life, in whom, therefore, on other grounds, such changes as are here referred to are likely to be met with.

*Symptoms and progress.*—The symptoms of paralysis agitans may come on gradually or suddenly. In the great majority of cases the onset of the disease is insidious. The part attacked is the hand or foot, or the thumb. If the hand be affected, its different segments oscillate on one another in a manner which is almost distinctive. The thumb moves on the other fingers as in the act of twisting wool, rolling a pencil, or crumbling bread. If the affection involve also the rest of the upper extremity, these movements of the fingers are associated with similar rapid backward and forward movements of the hand as a whole on the

forearm, and of the forearm on the upper arm. At this period of the disease the trembling is often transitory. It comes on occasionally only and may be at long intervals. It comes on, moreover, when it is least expected—when the patient is at complete rest, mentally and bodily; and it may be arrested by an effort of the will, and often ceases when he walks, or when he uses the affected limb for writing, lifting a weight, or other purposes. The trembling may be confined for an indefinite time to the part first attacked. But it generally spreads sooner or later: first, if a part only of a limb have been involved, to the rest of the limb, and subsequently, and often after longish intervals, to other limbs. It usually assumes in the first instance the hemiplegic form, affecting first the arm and then the leg of the same side, and extending later to the arm and leg of the opposite side. Sometimes it puts on the paraplegic character spreading from one leg to the other, before the upper extremities get involved. It seldom extends from one arm to the other, leaving the legs unaffected, or from the arm of one side to the leg of the opposite side. In some cases tremulousness is not the first symptom of which the patient complains. But its occurrence is preceded for a longer or shorter time either by a sense of profound fatigue, or by rheumatic or neuralgic pains referrible to the limb or part of a limb in which convulsive movements subsequently manifest themselves, or even by all the other characteristic symptoms of the disease. In rare instances the affection comes on suddenly, with tremulousness either of a single limb or of all the limbs. Under these circumstances it may subside at the end of a few days. But other similar attacks are liable to follow at decreasing intervals, until ultimately the disease becomes established. The duration of the initial stage to which the above account refers varies from one to two or three years.

When paralysis agitans has attained its complete development the trembling not only involves several limbs, and probably all of them, but is also (at all events in severe cases) almost incessant. It is liable, however, to remissions and exacerbations, the latter of which seem to be often induced by emotional disturbance or muscular exertion, yet not unfrequently come on without obvious cause. Natural sleep, or that induced by chloroform, is always attended with entire cessation from convulsive movements. It is at this period that the tremors put on their most distinctive characters. They consist of involuntary rhythmical oscillations, which have little amplitude, follow one another rapidly, and present considerable uniformity; and which, when the hand is involved, give to its different segments the aspect of being collectively engaged in the performance of some delicate process or operation. The head and neck remain, as a rule, free from convulsion. So far indeed from being agitated, the muscles of the face are immovable, the look is fixed, and the features present a permanent aspect of sadness or hebetude. The muscles of the jaw also generally are free from movement. Nevertheless, occasionally the head presents distinct rhythmical tremors, and the chin and lower lip even may be affected by independent tremors of their own, especially

observable when the mouth is open. The tongue also, when protruded, not unfrequently presents well-marked tremulousness. It is important to observe that occasionally the characteristic tremors of shaking palsy are absent from first to last. Nystagmus, so common in disseminated sclerosis, is absent here. There is no real failure of language, but speech is slow, hesitating, laborious, as though the enunciation of each syllable were attended with considerable effort. It may, however, become tremulous in consequence of the transmission of the tremulousness of the limbs to the head and neck. The voice, as Dr. Buzzard points out, is apt to assume a shrill, piping character. Deglutition is performed without difficulty, but is perhaps somewhat slow; and often in old cases saliva tends to accumulate in the mouth. Respiration does not suffer.

A striking phenomenon of the disease, to which Charcot has especially called attention, is rigidity of the muscles, which comes on for the most part late in the malady, though occasionally at its commencement. It affects the muscles of the extremities, trunk, and neck. The supervention of this rigidity is attended with cramps, followed by contraction, which is at first transitory, but after a time becomes persistent, though even then liable to exacerbations. The flexor muscles suffer in the chief degree. The rigidity and contraction, becoming permanent, give a peculiar aspect to the patient. The head is thrown strongly forwards and fixed in that position; and the trunk, when the patient stands, is bent in the same direction. The elbows are separated a little from the trunk; the forearms are slightly flexed on the upper arms; and the hands, similarly flexed on the forearms, rest upon the waist. The hands, moreover, are more or less deformed; usually the fingers are slightly flexed in mass at the metacarpo-phalangeal joints, with an inclination to the ulnar side of the arm, and with the thumb resting against the forefinger as in the ordinary position for writing; but in some cases the fingers, though substantially occupying the same position, are flexed at the proximal and distal joints, while extended at the middle joints. The rigidity of the lower limbs is such as sometimes to give the appearance of paraplegia with contraction; the feet are occasionally in the position of talipes equinovarus, and the toes bent into the form of a claw. The patient, however, retains the power of voluntary movement, and the muscles are never thrown into the tetanic spasms which are so common in many spinal diseases.

The difficulty of movement which characterises patients suffering from shaking palsy is due no doubt in some degree to the muscular rigidity and contraction which have just been described. But it often manifests itself long before the rigidity has become particularly obvious.

The same peculiarity attends speech. It would seem that unwonted efforts are needed for the transmission of the motor impulses; and indeed the slightest movements are followed by extreme fatigue. This group of phenomena has been taken to imply the existence of true paralytic weakness. But it is not so, for, on testing the strength of different limbs by the dynamometer, it has often been found, that (excepting in the case of patients in the last stage of the malady) muscular force is remarkably

preserved. Sometimes, indeed, the muscles of the most tremulous and apparently weakest limb are really more powerful than those of its seemingly healthier fellow.

The mode of walking in paralysis agitans is usually highly characteristic of the disease. The patient rises perhaps with difficulty from his seat, then steadies himself for a few seconds, and at length, with his head and trunk in advance, runs straight forwards, in spite of himself, with rapid steps. He appears to be losing his equilibrium, and running forwards to regain it; and not unfrequently he falls down. This difficulty of maintaining his balance in walking is not wholly due to the position which his body generally assumes, for it may occur while he is yet capable of retaining the erect posture; and, further, in some cases the patient has a tendency to fall or run backwards even when his body is bent forwards. Neither is it connected with the presence of vertigo, for the patient does not, as a rule, suffer from this sensation. This latter tendency (or retropulsion as it is sometimes termed) may sometimes be evoked by slightly pulling the patient's dress from behind when he is standing or walking forwards.

Various other symptoms besides those which have been enumerated complicate the course of shaking palsy. Patients usually complain of a sense of persistent tension or traction in the affected muscles, or of cramps; they experience a feeling of prostration or utter fatigue which especially comes on after fits of trembling; or they are the victims of an undefinable *malaise* or fidgetiness. They want incessantly to shift their position; and if they be not assisted in their desire, their sufferings become unendurable. They suffer most in this respect at night and when in bed. Another cause of suffering is an habitual sensation of excessive heat, referred mainly to the epigastrium and back, but not limited to these situations. It varies in intensity, and is usually most severe after the occurrence of a paroxysm of trembling. It is not attended with any actual elevation of temperature. Cutaneous sensibility is in no degree affected. The patient retains his mental faculties and the power over his rectum and bladder.

The final stage of the disease supervenes for the most part at the end of some years. It is indicated: by aggravation of the difficulty of movement, the patient being consequently compelled to keep his room or his bed; by failure of nutrition, in which the muscles chiefly suffer, occasionally becoming fatty; by impairment of intelligence or of memory; by general prostration; and by the formation of bed-sores. At this time the convulsive movements not unfrequently cease. Death results sometimes from gradual asthenia, more commonly from the supervention of some other disorder, especially pneumonia. The duration of the disease may extend to twenty or thirty years.

*Treatment.*—All kinds of treatment have been employed, but for the most part with little success. Among the medicines which have been recommended may be named iron, nitrate of silver, chloride of barium, arsenic, zinc, strychnia, ergot of rye, belladonna, opium, hyoscyamus, and Calabar bean. Of these iron is advocated by Elliotson, and has perhaps

been instrumental in improving the general health of patients; and strychnia has been lauded by Trousseau, but seems to have been found injurious by Charcot. The only one of the sedative drugs which the latter authority thinks serviceable is hyoseyamus, and this effects no permanent improvement. Warm baths, cold baths, and shower baths are also sometimes of temporary service. Electricity has been largely employed, but the only form which seems to have been of real efficacy is the constant current. A few cases of recovery under its use have been recorded. It must not be forgotten, however, that cases which have not advanced beyond the early stage occasionally get well spontaneously. On the other hand, this fact justifies the hope of benefit from judicious treatment. Hygienic measures should never be neglected.

---

### VIII. PSEUDO-HYPERTROPHIC PARALYSIS

*Definition.*—This is a form of paralysis, first recognised and described by M. Duchenne, occurring mainly in children, and attended with remarkable enlargement of some of the paralysed muscles.

*Causation.*—The disease may be regarded as one of childhood, and occurs almost exclusively in boys. Occasionally several children of the same family are attacked. Two or three cases are recorded in which it began in adult life. Beyond these facts nothing whatever is known in reference to its causation.

*Morbid anatomy.*—The morbid process, so far as the muscles are concerned, appears to consist mainly in the gradual growth of connective tissue in the interstices between the ultimate fibres; this becomes abundant and dense, and in some cases the seat also of the formation of fat. It is to this overgrowth that the apparent hypertrophy of the muscles is due. The muscular fibres appear to dwindle away under the influence of the pressure to which they are subjected; and, although retaining their transverse striation for a long period, at length undergo degenerative changes the striae becoming indistinct, or effaced, longitudinal markings perhaps unusually apparent, and more or less abundant deposit of granular or fatty matter taking place. The condition of the muscles in the earliest stage of the disease has been less thoroughly investigated than their condition in the later periods. M. Duchenne believes that at that time there is an oedematous state of the tissue which itself causes a certain amount of increase of volume.

*Symptoms and progress.*—The course of pseudo-hypertrophic paralysis has been divided by M. Duchenne into three periods. Of the first but little is certainly known, for its symptoms are slight, and children are rarely at that time brought under medical treatment; moreover, the symptoms are in no degree distinctive of the disease, and are apt therefore to be misunderstood. The first symptoms appear to be due to gradual enfeeblement of the muscles of the lower extremities, and perhaps of those of the back. The child presents certain peculiarities of gait. He

stands with his legs widely separated and his shoulders thrown back, probably beyond the buttocks, the concavity of the small of the back being correspondingly deepened; he also walks with his legs apart, lifting the knee of his advancing leg needlessly high, while the foot is extended, and the toes point downwards, and swaying his body from side to side in association with the peculiar position and movement of his lower extremities. This stage, according to M. Duchenne, usually varies in duration from a few months to a year. It may, however, be delayed, or it may so speedily merge in the second stage as to be unappreciable.

FIG. 106. Portrait of a boy suffering from pseudo-hypertrophic paralysis.

The second stage is marked by the gradual extension of the disease and the enlargement of certain muscles. The paresis, which probably always commences symmetrically in the lower extremities, gradually mounts, involving successively the muscles of the back and of the trunk generally, the muscles of the arms, and in some cases those of the face—more especially the temporals and masseters. Possibly some fulness of the calves may already have been apparent in the first stage; but now they augment rapidly and considerably in volume; and by degrees various other groups of muscles become similarly affected. The degree of enlargement and its distribution differ in different cases. In some, only the calves become hypertrophied, while the muscles of the rest of the body either retain their normal bulk or shrink; in some the calves and buttocks are the chief seats of

overgrowth; in some the increase of bulk involves all the muscles of the lower extremities together with the posterior muscles of the spine; in some again, the deltoids share in the widely diffused hypertrophy; and occasionally all the muscles of the limbs and trunk become enormously increased in volume, and the child (though so feeble, perhaps, that he can scarcely move) acquires the appearance of an infant Hercules. This enlargement of the muscles, even if it be limited to the calves, is a very striking phenomenon; especially when, as in these cases, it goes along with progressive loss of muscular power. During the progress of this stage the phenomena which have already been referred to as attending the acts of standing and walking become more pronounced; the legs are kept widely apart; the shoulders are thrown far backwards, sometimes also the head and neck, as in opisthotonos; and the peculiar swaying of the body from side to side, which attends the efforts to raise and project the legs successively forwards, becomes considerably exaggerated. Moreover, the child has the greatest difficulty in rising from the ground on which he is sitting into the upright posture; he gets on all-fours, then protrudes his buttocks like a dog in the act of stretching, and probably finds all his efforts fruitless unless he can manage to raise his head and

shoulders hand over hand by means of a chair or bedstead. This stage attains its full development in a year or a year and a half, and may then continue with little change for two or three years more.

The third stage is characterised by extension of paralysis to the upper extremities, supposing these to have escaped hitherto; by arrest of the progressive enlargement of the muscles; and possibly even by their diminution. The child grows more and more limp and helpless; the voluntary elevation of the arms becomes difficult and at length impossible, and he gradually loses all power in his lower extremities, and is hence condemned to pass the rest of his existence on his chair or in bed. Since respiration, circulation, and digestion remain unaffected, life may be sustained in this condition for a considerable period; but sooner or later the vital powers of the patient become prostrated, and pneumonia or some other intercurrent affection carries him off. Death usually occurs during the period of adolescence.

In order to complete the picture of the disease, two or three other facts in relation to these patients must be mentioned. No febrile symptoms manifest themselves at any period of the disease. The muscles in the early stage retain their electro-contractility almost unimpaired; later, faradic contractility undergoes diminution, while galvanic contractility either still remains unaffected or becomes increased. Tendon reflexes disappear in the second stage. It has been shown by Dr. Ord that the temperature of the legs, in cases in which the calves are hypertrophied, is three or four degrees higher than that of the thighs, a fact which he connects with the active growth of fibroid material taking place between the muscular fasciculi. It has often been observed that children afflicted with this disease are, or become, defective in their intelligence; and that, if they be attacked before they have learned to speak, they are slow in learning to speak, and imperfect in their articulation. Lastly, there is no impairment of sensation, and no loss of control over the bladder or rectum.

*Pathology.*—Notwithstanding the symmetrical character of pseudo-hypertrophic palsy, its tendency to become generalised, and its association with impaired intelligence, there is no sufficient reason to regard it as of nervous origin. For no lesions have been detected in the nervous centres or in the nerves sufficiently constant or definite to allow of their being regarded as primary or essential, while the absence of rigidity, incoordination, and rapid wasting, and the retention of sensation, control over the sphincters and muscular contractility, equally point to integrity of the spinal cord. On the other hand, in the muscles themselves progressive changes have been discovered which are ample to explain the main phenomena of the disease.

*Treatment.*—According to M. Duchenne, pseudo-hypertrophic paralysis may sometimes be cured or arrested in its first stage by muscular faradism, aided by baths and kneading, or shampooing. When once, however, distinct enlargement of muscles has taken place, no treatment that has yet been adopted avails to delay the fatal progress of the disease.

## IX. THOMSEN'S DISEASE

*Definition.*—An affection first fully described by Thomsen (himself a sufferer), characterised by transient rigidity of the voluntary muscles coming on only when they begin to act.

*Causation.*—Nothing is known of the origin of this disease beyond the facts—that it is distinctly hereditary, that it is apt to attack brothers and sisters, and that (at any rate in nearly all cases) it is congenital.

*Symptoms and progress.*—The symptoms sometimes manifest themselves in early infancy; but for the most part are not recognised until the age of four or five. They may, in slight cases, not even be observed until the period of puberty. They usually become more and more marked as growth proceeds and then remain stationary. The characteristic feature of the disease is the occurrence of a brief check to the use of the voluntary muscles coming on at the moment when it is first attempted to put them in action after rest. The muscles become rigid, intended motion is arrested or impeded, the patient becomes for a brief space more or less helpless, and sometimes absolutely helpless. The duration of the hitch may be momentary or may last for some seconds or even a minute or two; and it may recur with diminished intensity when a fresh attempt to move is made. But when once the rigidity is overcome the patient's movements remain perfectly free; and he may continue to walk or to take part in athletic sports for an indefinite period; or until, after some brief rest or in the attempt to bring unused muscles into play, the initial spasm recurs. The spasm, as in the case of stammering, is more likely to occur, or to become aggravated, when the patient is nervous or his attention is specially directed to his infirmity. The tendency to spasm is usually limited to the upper and lower extremities, the legs suffering most. But in some cases the muscles of the face, of mastication, of the tongue, or of the eyeballs, partake in the affection. The muscular system is always well developed; not unfrequently indeed the muscles are of Herculean bulk, and unusual strength.

Careful investigations of the muscular phenomena have been made by Erb and others. 'In his (Erb's) case, a single brief effort caused tonic contraction, which lasted for twenty-five seconds. Momentary electrical stimulation of the nerves caused only a momentary contraction of the muscles, but continued stimulation caused a prolonged contraction similar to that excited by the will. In certain muscles, moreover, an unbroken current caused peculiar wave-like contractions, about one per second, passing from the negative to the positive pole. Any strong stimulation of the muscle itself caused a similar after-contraction. The irritability of the nerves was normal, but the voltaic excitability of the muscles was unduly great, and they were remarkably sensitive to mechanical stimulation. Firm pressure caused a tonic contraction lasting from twelve to twenty seconds.' (Gowers's 'Manual of Diseases of the Nervous System.')

No structural changes of any importance or competent to explain the phenomena of Thomsen's disease, have been discovered. The muscular

tissue has usually been found absolutely healthy ; but in some cases the individual fibres have been obviously larger than normal. The central nervous organs and the nerves appear to be healthy. It is generally considered that the symptoms are due to some functional disturbance of the muscles themselves. There is obviously some derangement of the functional relations between the muscles and the nervous apparatus which ministers to their action.

The disease is incurable, but exercise is said to be beneficial.

---

## X. MORBID GROWTHS. ANEURYSMS. ENTOZOA

Various forms of adventitious growths affect the nervous centres or structures in relation with them. It is quite impossible, however, to distinguish them from one another during life by reference simply to the nervous symptoms which they induce. It is needless, therefore, for clinical purposes, to discuss each variety separately ; and we shall content ourselves with first giving a brief sketch of some of the most striking pathological phenomena which the more important forms of growth present, and then discussing the clinical history of such tumours as a whole.

*Morbid anatomy.*—1. *Tubercle.* In a strictly scientific arrangement of disease we ought, of course, to include under this head miliary tubercles of the pia mater. We have considered these, however, elsewhere in association with meningitis, which they generally induce, and independently of which they rarely if ever cause symptoms. The variety of tubercle which we have now specially to consider is that which originates within the nervous substance and forms tumours there, varying from the size of (say) a pin's head to that of a fowl's egg. They are well-defined, rounded, or lobulated masses, opaque, of a yellowish or greenish tinge, with much of the consistence and aspect of cheese. They correspond pretty exactly to the description usually given of typical yellow or crude tubercles ; but, although they may disintegrate at points, they seldom, if ever, break down into cavities. They are made up of aggregations of smaller masses, and differ in no important respect from the tubercular aggregates which in cases of tubercular meningitis are found along the vessels or in the depths of the sulci, and are the results of the coalescence of miliary tubercles. They may be solitary, or may exist in large numbers, and they may occur in any part of the nervous centres, involving, however, by preference the grey matter both of the brain and of the cord. No doubt, from their large size, the cerebral lobes are pre-eminently liable to suffer. But tubercles have also a remarkable aptitude to form in the substance of the cerebellum ; and then (according to Andral) in the ascending order of frequency in the pons, medulla oblongata, spinal cord, peduncles of cerebrum and cerebellum, optic thalami, and corpora striata. They are much more common in the upper part of the cord than in the lower part. Tubercular tumours of the brain appear to occur more frequently in boys than girls, and are rarely met with either in adults or in children under two years of age.

They occur most commonly between the ages of three and seven. Tubercle of the nervous centres is probably always associated with tubercle in other parts; and, although ordinarily there is no connection between them, tubercular meningitis sometimes supervenes on the presence of tubercular masses of old date in the substance of the brain.

2. *Syphilis*.—The ordinary seat of intracranial syphilis is the dura mater. The disease may involve the outer aspect of that membrane, in which case it is usually associated with disease of the bones of the skull, and affects the brain mainly by pressure. Or it may involve the substance of the membrane, or its inner aspect, leading to the development of hard, dense gummata, which may be solitary or multiple, localised or scattered over a considerable extent of surface, and may vary individually from the size of a hazel-nut downwards. These tend gradually to involve the contiguous structures. The visceral arachnoid becomes adherent to them, and not unfrequently similar growths then develop in the subarachnoid tissue and pia mater. Subsequently the subjacent brain suffers, becoming first indented, and then either softened or the seat of gummatous growths. The parts of the dura mater which are most commonly affected are those corresponding to the convexity of the hemispheres, and those in relation with the anterior and under-surface of the brain, more especially in the neighbourhood of the sella turcica, whence the disease may spread to the surface of the petrous portions of the temporal bones and to the tentorium cerebelli.

Gummatous tumours originating in the pia mater or in the substance of the brain are much less common than the last, and, as a rule, are softer and more transparent and jelly-like; they are usually of small size, but may attain the bulk of a hen's egg. Those which are developed primarily from the pia mater affect mainly the under-aspect of the brain, more especially between the optic commissure in front and the pons behind, and in the course of the cerebellar peduncles. These, too, are the situations in which they attain their greatest bulk. Syphilitic disease of the membranes sometimes results in the formation of dense cicatricial patches, with adhesion between the several laminae and more or less implication of the subjacent brain-substance or of nerves.

Tumours of the substance of the brain arise chiefly in the hemispheres and the larger ganglionic masses, especially the optic thalami. After these parts they affect mainly the pons Varolii and the cerebral and cerebellar peduncles. It is an important fact that syphilis, whether of the dura mater pia mater, or nervous tissue, has a marked tendency to affect the parts at the base of the brain, and consequently to implicate the nerves there situated.

Although there are good clinical reasons for believing that the cord and its membranes are not unfrequently the seat of this disease, there are but few published cases in which the diagnosis has been verified by post-mortem examination.

It is not rare for the cerebral arteries in connection with syphilitic growths to become obstructed with thrombi; but it also not unfrequently happens, in cases of secondary or tertiary syphilis, that, independently of

the formation of gummata, the walls of certain of the arteries at the base of the brain become thickened, indurated, and translucent, and the channels subsequently obstructed, partly from this thickening of the walls, partly from thrombosis.

3. With respect to other neoplastic formations, notwithstanding the importance and frequency of some of them, we need not, for many reasons, go into much detail. They are mainly the following: fibroma, psammoma, melanoma and cholesteatoma (to which, on account of their rarity or of their insignificance in a clinical sense, we shall make no further reference), and myxoma, glioma, sarcoma, and cancer.

*a. Myxomatous tumours* are not altogether unfrequent. They sometimes originate in the membranes of the brain or cord, sometimes in the cerebral substance. Their most common seat, however, is the cerebral hemispheres, where they form transparent gelatinous growths which often become cystic, and tend to acquire large dimensions. They may attain the size of a man's fist.

*b. Gliomatous tumours*, also, are not unfrequent, and, indeed, are almost special to the nervous centres. They are greyish or pinkish in tint, translucent and highly vascular, infiltrate, as it were, the tissues in which they are found, and blend insensibly with them at their edges. Moreover, though varying somewhat in colour, transparency, and density, they have a considerable resemblance to the grey matter of the nervous centres. There are two forms of glioma, the one hard, the other soft. The former has a considerable anatomical resemblance to simply sclerosed tissue; the latter, which is the more common, blends on the one hand with myxoma, on the other with small round-celled sarcoma. Gliomatous tumours of minute size sometimes stud the ependyma of the ventricles. They are usually found, however, in the substance of the hemispheres, more especially in their posterior lobes and in their upper and lateral parts. But they may be met with elsewhere in the nervous centres, and even in the spinal cord. They are for the most part solitary, of slow growth, and apt to attain a large size, as that of the fist, or even of the foetal head. Owing to the great vascularity of the softer forms of tumour, they are liable to attacks of congestion, and to more or less abundant internal hemorrhage.

*c. Sarcomatous tumours* occur both in the dura mater of the brain and cord, and in the substance of these centres. They vary widely in their microscopical structure and in their aspect and rapidity of growth. But they may be divided roughly into two forms—hard and soft. The former has some resemblance to fibroma, the latter is usually more or less translucent, white or grey, vascular, and, from its general resemblance to brain-substance, has been termed, in other organs than the brain, cerebriform. Sarcoma of the cerebral dura mater generally occurs at the base, in the neighbourhood of the sella turcica or petrous bones; that of the theca vertebralis affects no special seat. Sarcoma originating in the nervous tissue is usually of the soft form and solitary, and often grows to a large size. In the brain its usual seats are, not the hemispheres, but the optic thalami, corpora striata, corpora quadrigemina, pons, cerebral peduncles

and cerebellum. It is only occasionally met with in the substance of the cord. Sarcoma originating in the nervous centres is seldom, if ever, malignant; the solitary tumours, therefore, which have just been considered, are not associated with the presence of similar tumours in other parts. On the other hand, it must not be forgotten that malignant sarcomas (melanotic and other) of other organs are apt to be attended with multiple secondary tumours in the substance of the brain. Primary sarcoma of the brain is mostly a disease of early childhood.

*d. Carcinomæ* of the nervous centres, and of the parts about them, was formerly believed to be of common occurrence; but by all authors up to a recent date, sarcoma, glioma, and probably other forms of tumours, were all regarded as varieties of it. Carcinoma, in the restricted sense of the term, originates rarely if ever in the brain or cord, and not often in the bones and soft parts immediately surrounding them. Frequently, however, during the period of generalisation, it involves all these parts, and hence scirrhus, encephaloid, and melanotic tumours are not uncommon as secondary occurrences in the brain or cord, and in the membranous and bony parietes of these organs. Cancerous tumours therefore are generally multiple, and seldom reach a large size. Carcinoma of the skull, vertebræ, or periosteum of these parts is apt in its progress to reach the surface of the brain or cord, and to involve these organs either by pressure or by direct extension; it is especially apt, moreover, to constrict the bony channels by which the nerves escape, to implicate the nerves and finally to destroy them.

4. *Entozoa*.—The only entozoa which infest the brain of man are the cysticercus cellulosæ and the hydatid.

*a.* Although a considerable number of cases of cysticerci of the nervous centres are on record, they are met with very rarely. The cysts, which are of the size of a pea or horse-bean, vary in number from one or two to a hundred or more, and they occupy either the subarachnoid tissue, the choroid plexuses, or the nervous parenchyma. In the last case they are most common in the cerebral hemispheres; but they have been met with in the cerebellum, medulla oblongata, and other parts.

*b.* Hydatids of the brain are rare. They are generally solitary; but a couple or more have been found in the same case. They are almost always barren. Their size varies; but they not unfrequently attain a couple of inches in diameter before they cause death, and may be much larger. They generally occur in the substance of the cerebral hemispheres, but have been found in the cerebellum, and elsewhere in the nervous parenchyma. They also affect the meninges, and have been discovered in the lateral ventricles, and in the subarachnoid tissue of the cord. They seldom cause inflammatory changes in the surrounding parts, or other mischief than that arising from simple pressure. Neither do they appear ever to become the seat of suppuration. Hydatids of the brain are not unfrequently associated with hydatids of the liver or other organs. They are said to occur chiefly in persons between ten and twenty years of age.

5. *Aneurysms of the arteries of the base of the brain*.—We speak of

these now only as tumours, and because from their bulk and situation they are exceedingly liable to interfere with the functions of important parts. They arise chiefly in the internal carotid arteries and their middle cerebral branches, and in the basilar; but they may also be found in other vessels, such as the anterior and posterior cerebrals, the anterior and posterior communicating branches, and at the bifurcation of the basilar. An occasional seat is that portion of the internal carotid which lies within the cavernous sinus. They usually vary in size from that of a pea to that of a marble, but have been met with as large as a hen's egg. From their position they are liable to compress some of the nerves at the base of the brain, and to indent the surface of the brain itself. They usually occur in persons over forty, but they have been met with even at the age of puberty. Males are more liable to them than females.

*Symptoms and progress.*—1. *Brain.* The symptoms referrible to tumours involving the brain present the greatest variety—a statement which is not likely to be disputed when one takes into consideration the various circumstances under which tumours arise, the different proclivities of different tumours, and the wide range of functionally distinct parts of the surface or substance of the brain which they may implicate. It is impossible, indeed, to draw up any scheme of symptoms generally applicable to cases of the kind; and we purpose, therefore, to consider *seriatim* the more important symptoms which the presence of cerebral tumours may induce.

*Vertigo* is generally present at some period or other. Sometimes it is the first symptom of which the patient complains, and often it is the most constant.

*Headache* is, with rare exceptions, a prominent symptom. In most instances it is, in association with vertigo and occasional vomiting, one of the earliest symptoms. It is often persistent, but liable to exacerbations; sometimes only comes on at irregular intervals. It may be little complained of, or even wholly absent, but is usually severe, and often unbearable. It varies in character; is sometimes a sense of constriction or pressure, sometimes a feeling as though the head would burst, sometimes shooting, aching, or boring. It is referred to different parts in different cases; sometimes affects the vertex, forehead, or occiput mainly; sometimes shoots through the ears or temples—in the latter case probably involving the eyeballs, and associated with intolerance of light. The situation of the pain is no sure guide to the seat of disease; nevertheless pain referred to the occiput and back of the neck is not unfrequently connected with disease in the posterior fossa of the skull; and it is believed by some that percussion excites especial pain in that part of the skull beneath which a tumour lies.

*Vomiting* is a common symptom of many cerebral diseases, and is often an early indication of the presence of cerebral tumours. Indeed, it is well known, especially in reference to the tubercular tumours of children, that unaccountable vomiting is often the first warning of the affection which is in progress. The sickness often comes on at irregular intervals, without obvious cause, is not unfrequently attended with nausea or loss of appetite,

and is generally associated with constipation. It may continue on and off during the whole of the patient's illness, but is mainly a symptom of the earlier stages.

*Slowness of pulse*, with more or less irregularity, is of frequent occurrence, more especially during the period of invasion; subsequently also the same condition of pulse may prevail. But, on the other hand, it is then often of normal rate, or increased in frequency.

*Hemiplegia and hemianæsthesia*.—Hemiplegia is no doubt entirely absent in a large number of cases, and when present usually comes on insidiously during the later stages. There is, however, great variety as regards this symptom. In some instances almost the first indication of disease is an apoplectiform or epileptiform fit followed by hemiplegia. In some the attack of hemiplegia comes on suddenly in the course of other symptoms. And in either of these cases more or less complete recovery from the paralytic phenomena may ensue, to be followed by a relapse or by a series of recoveries and relapses. The hemiplegia generally follows the rule of ordinary hemiplegia in the fact that the arm is more affected than the leg, and the lower distribution of the seventh nerve than the other motor nerves of the face. But occasionally the paralysis is slight or limited, and reveals itself only in the face or arm. It may or may not be associated with numbness, tingling, or anæsthesia of the paralysed parts, or with hyperæsthesia, tenderness, or pain. Rigidity and contraction of the affected limbs may supervene.

*Local paralyses* are very common, sometimes in association with hemiplegia, sometimes independently of it. They are generally due, not as hemiplegia or hemianæsthesia is, to disease involving the opposite corpus striatum, optic thalamus, or cerebral hemisphere, but to direct implication by pressure or by involvement in the morbid process of the nuclei of origin of the affected nerves or of the nerves themselves. If, therefore, they be due to the same mass that causes hemiplegia, they occur on the opposite side of the body to the hemiplegia. But more tumours than one are not unfrequently present, and tumours of the crura cerebri, pons, or medulla, or growths in the neighbourhood of the circle of Willis, may readily involve directly several nerves of either side, even when causing at the same time distinct hemiplegic phenomena. In some cases there is paralysis of one or both external recti, leading to single or double internal squint; in some paralysis of the whole or a part of one of the third nerves, involving ptosis, with paralysis perhaps of the internal rectus, and an outward squint; in some the portio dura suffers, and Bell's paralysis is the consequence; in some the spinal accessory is affected and laryngeal paralysis ensues, probably associated with paralysis of the corresponding arch of the fauces; in some the hypoglossal becomes implicated. It is important, in reference to these local paralyses, to bear in mind that, contrary to what occurs in ordinary hemiplegia, the faradic contractility of the affected muscles rapidly disappears, and acute wasting is apt to ensue.

*Implication of sensory nerves*.—The fifth nerve occasionally suffers, either generally or in some of its branches; in some instances intense

burning or neuralgic pains arise, in some tingling, numbness, or absolute anæsthesia. In the last case the surface of the eye, among other parts, becomes insensible, and consequently unconscious of irritation and liable to inflame. Sometimes from implication of one or both olfactory nerves, or one or both gustatory nerves, the sense of smell or taste is lost on one or both sides. As regards the ears, there is not unfrequently more or less deafness, with buzzing, rushing, or singing noises; and absolute deafness on one or both sides may ensue. The most interesting and important complications, however, are those which involve the visual properties of the eyes. We have alluded to the fact of the occasional occurrence of double vision and of intolerance of light. But, besides these phenomena, we often meet with obscurity of vision, which may go on to complete blindness, in one or both eyes; hemianopia, the field of vision being eclipsed in the identical halves of both retinae; the appearance of muscæ; and other visual derangements. The presence of cerebral tumours is, moreover, almost always associated with optic neuritis, which may after a time result in atrophy of the optic disc. The same rule applies to paralyzes of individual sensory nerves as to paralyzes of individual motor nerves: they are usually due to direct implication of the nerves or of their nuclei, and are observed therefore on the same side of the face as the cerebral tumour which causes them. The question whether they be dependent on local causes or on disease of the nervous centres above their nuclei can, in doubtful cases, generally be determined by the fact that in the former case reflex phenomena cease, in the latter they may be readily excited (M. Jaccoud). If, for example, the disease causing blindness be in the optic nerve, the pupil will be dilated and will remain dilated when exposed to light; while, if it be situated above the corpora quadrigemina, the patient, though equally blind, will have free action of the pupil under the influence of the ordinary stimuli.

These various local sensory and motor affections may come on at any period of the disease; they are liable to appear and disappear before they become permanent; and they tend to increase in degree and in number with the advance of the disease.

*Convulsions and spasms.*—These, though not always present, constitute some of the most striking phenomena of cerebral tumours. They may be tonic or clonic, limited to the distribution of a single motor nerve, or implicating a group of muscles, a limb, the head and neck, or one side of the body. They may come on rarely and at distant intervals, or in frequent daily paroxysms, or may be almost continuous. And in either case they are apt to disappear wholly for a time, or to cease altogether. They are often distinctly epileptiform in character; but, unlike true epilepsy, are often unattended with loss of consciousness; or loss of consciousness comes on in the course of the attack instead of at the beginning. It is in cases of this kind, rather than in cases of simple paralysis, that, as Dr. Hughlings Jackson has shown, the seat and distribution of the peripheral phenomena point to the implication of definite cerebral areas.

*Intellectual and emotional disorders* present great variety. In some

cases one of the earliest indications of cerebral tumour is the occurrence of attacks, sometimes momentary, of incoherence, delirium, failure of speech or loss of consciousness, associated or not with some partial convulsive movement or paralysis, or of attacks which may exactly simulate hysterical fits or apoplectic seizures. On the other hand, these may be delayed until a late period of the disease, and may occur only as the immediate precursors of death. Sometimes they come on at long and irregular intervals; sometimes they are very frequent, occurring many times a day, and even in long-continued sequences. In a large proportion of cases the patient suffers from gradually increasing failure of memory and hebetude; he becomes aphasic or incoherent, or fatuous, and under such circumstances possibly loses, or fails to exert, control over his evacuations; or he gets delirious or maniacal; and, associated with some of these mental derangements, we not unfrequently find him either given to boisterous laughter, or low-spirited and apt to cry.

*Obstruction of venous sinuses.*—Cerebral tumours occasionally cause obstruction either of the cavernous sinus or of the sinuses between this and the internal jugular vein; and, as a consequence, the veins of the eyelids and of the corresponding side of the forehead become more or less obviously distended. Similar dilatation of veins sometimes occurs in these cases, even when no obvious obstruction is present.

Lastly, it may be pointed out that bed-sores are often developed sooner or later: occasionally early, in connection with the occurrence of irritative or inflammatory processes; more frequently late, when the patient is bedridden, paralysed, and demented.

We repeat that the symptoms due to cerebral tumours display remarkable diversity; nevertheless, careful attention to all the phenomena of the case will generally allow of a fairly accurate diagnosis being made. The onset of the disease may be gradual or sudden; and the symptoms which attend it may be of the most varied kind. The subsequent progress of the case is equally uncertain; sometimes the symptoms increase progressively and rapidly until death takes place: sometimes, and indeed in the great majority of cases, the patient is liable to remissions, or intervals of apparent restoration to health, though naturally such remissions tend to become less and less marked with the advance of the disease, until at length continuous illness is established: occasionally recovery apparently takes place. The duration of life from the first development of symptoms varies largely; sometimes the patient sinks at the end of a few weeks; sometimes death is delayed for several years. But the commencement of symptoms cannot always be determined—especially when the cerebral tumours complicate other diseases. The causes of death are various. In some cases the patient sinks from innutrition and the formation of bed-sores; in some he is carried off in an attack of convulsions; in most death is ushered in by coma.

It is not always possible to distinguish the symptoms of cerebral tumours from those caused by other affections of the same parts. Nor is this surprising when we bear in mind that many other diseases attack

districts of the brain which tumours also affect, and that these as well as tumours are liable to be attended with swelling, inflammation, and softening of surrounding parts, and to produce both general and local symptoms. Among the affections here referred to are apoplectic effusions, embolic softenings, abscesses of the brain, and chronic diseases of the dura mater.

The determination of the site of a tumour must rest upon a consideration of the various details of the paralytic and other phenomena which the patient presents; and especially we may here be guided by our anatomical and physiological knowledge, and the ascertained facts of cerebral localisation. In many cases we may come to a fairly accurate conclusion on these points. But it must not be forgotten that insuperable difficulties are often presented by the fact, either that tumours are multiple, or that they occupy some tract within the hemispheres, or at their surface, lesions of which are not necessarily attended with hemiplegia or any specific nerve-phenomena.

Our recognition of the nature of a tumour must depend partly on our knowledge of the circumstances under which different growths are apt to arise, partly on our knowledge of the parts of the brain which they are severally most prone to affect, and partly on the duration of the disease. *Tubercle* occurs chiefly in children; the cerebral phenomena due to its presence are often remarkably slow in their evolution; and the disease is generally associated with tubercular disease elsewhere. The cerebellum often suffers. Moreover, symptoms of tubercular meningitis are apt to supervene. *Syphilitic* tumours occur in adults who have usually either a distinct history of having contracted a chancre, or obvious traces of constitutional syphilis. They have, moreover, a remarkable tendency to affect the under part of the brain, and to involve the nerves there situated; to cause cephalalgia, defect or loss of smell, hemianopia, paralysis of oculomotor nerves, deafness, paralysis of the portio dura, bulbar palsy, and above all, perhaps, trigeminal neuralgia or paralysis, and, in connection with these, the nutritive lesions which have already been described. Further, it must not be forgotten that syphilitic patients are (even in the secondary period) liable to have sudden thrombotic occlusion of cerebral arteries, and symptoms identical with those attending embolism. Secondary *malignant* growths would be suspected if the patient were suffering also from a mediastinal tumour, or some form of malignant disease involving the skin, bones, mamma, uterus, or other organs. The presence of *hydatids* might be surmised if there were a total absence of all constitutional symptoms or taint and of all indications of local inflammation or softening, if moreover the patient were young, and especially if an hydatid tumour were detected in the liver or some other accessible organ. The symptoms due to *aneurysms* are generally much more obscure than from the position of the tumours might be supposed. Indeed, their presence is generally not suspected until their rupture causes apoplectic phenomena and death. Murmurs have occasionally been detected on auscultation in cases of aneurysm of the internal carotid or basilar; and occasionally also aneurysms of the internal carotid have communicated with the cavernous

sinus, leading to dilatation and pulsation of the veins within the eye and in the eyelids.

2. *Spinal cord*.—Tumours involving the spinal cord, its membranes, or the nerves which spring from the cord, cause symptoms due partly to the compression or destruction which they effect upon the substance of the cord, partly to involvement of the nerves, partly to local conditions of inflammation and the like.

a. Those which originate in the substance of the cord are attended with much the same symptoms as is compression of the cord connected with vertebral caries. They cause more or less complete paraplegia in the parts which derive their innervation from the portion of cord below; and the distribution and character of the paralysis will necessarily vary according as the tumour is situated higher or lower in the cord, and according to the tract which it primarily involves, and its horizontal extension. There are some points, however, in regard to these tumours which it is well to remember: their presence is rarely, if ever, attended with either central or peripheral pain; they originate mainly in the grey matter, and hence both sensation and motion are as a rule early affected; they commonly involve one side of the cord, or some other limited portion of the cord, in the first instance, and hence induce irregular or cross paralysis, so that during the earlier period of their development there is very likely to be motor paralysis on the side of the lesion, and anæsthesia on the opposite side; and the progress of the paraplegic symptoms is liable to remarkable remissions. It may be added: that, owing to certain peculiarities as to their primary site, it is possible that their first symptoms may simulate those of locomotor ataxy or those due to lateral sclerosis; that they tend ultimately to produce absolute paraplegia; and that, wheresoever originating, they are liable to be followed by ascending and descending degenerative changes, and by spasms and contractions of the affected muscles, with more or less rapid wasting of some of them.

b. Tumours taking their origin in the meninges of the cord are apt at a very early period to implicate the sensory or motor roots of the nerves which are in relation with them. Hence arise (and sometimes before any paraplegic symptoms are developed) twitchings of certain muscles, followed by paresis, paralysis, and rapid wasting, and burning or quasi-neuralgic pains referred to the peripheral distribution of certain nerves (it may be in the first instance to a single spot)—pains which are subject to great variations, are often exceedingly intense, and are occasionally attended by cutaneous eruptions. The paraplegic symptoms of such cases are usually undistinguishable from those accompanying vertebral caries, and are (at all events in the first instance) due to compression of the cord alone. It is obvious that the distribution of the paralytic phenomena, and the order of their sequence, must depend largely on the position of the tumour and the direction in which pressure on the cord is applied.

c. Tumours which are primarily developed in the tissues external to the membranes, more especially therefore aneurysms and malignant growths, usually involve the sensory and motor nerves in the neighbour-

hood of their origin long before they involve the cord itself. These, far more even than tumours originating in the meninges, are thus apt to induce severe sensory and motor troubles of limited distribution. The pain which they provoke is burning, wrenching, or crushing, constant, but liable to frequent exacerbations, which are often quite beyond endurance, and during which the patient grinds his teeth, groans, or actually shrieks. It is often attended with hyperæsthesia of the affected surfaces, and probably followed after a while by circumscribed anæsthesia, and by bullous or erythematous eruptions. The motor troubles are mainly paresis, and rapid wasting and contraction, of certain groups of muscles, with abolition of the tendon reflexes. The above phenomena occur with special intensity in cases of carcinoma involving the bodies of the vertebræ, owing partly to the tendency of the affected bodies to collapse, partly to the tendency to direct implication of the nerves. They are apt, moreover, not only to be exceedingly acute, but to have a comparatively wide distribution. Symptoms due to compression of the cord come on (if they come on at all) at a later period.

Assuming the presence of a tumour, its nature can only be determined in certain rare cases. If tubercle be ascertained to exist in other organs, we have some reason to suspect that associated paraplegic symptoms (if not due to vertebral caries) are due to a tubercular mass in the substance of the cord. If paraplegic symptoms come on during the reign of constitutional syphilis, we may have in that association a clue to the nature of their cause. If they be preceded by agonising pain, such as has been above described, we have grounds to suspect the presence of some tumour involving the vertebræ; and if they come on in the course of mammary or abdominal cancer, and especially if we find the spine presenting some localised obtuse bend in the neighbourhood of the point from which pain radiates and paraplegic symptoms begin, we have confirmatory evidence of the strongest kind.

*Treatment.*—The treatment of tumours, whether of the brain or cord, must be for the most part simply palliative. We must endeavour to relieve sickness by some of the various methods which are usually had recourse to for that purpose; to alleviate pain, either by the application of cooling lotions, ice, aconite, belladonna, or other sedatives, to the seat of pain, or by the internal exhibition of sedatives or narcotics, especially Indian hemp or opium; to calm convulsions or mental excitement by suitable remedies; to promote appetite; to keep the bowels free, and the patient clean; to prevent the formation of bed-sores; and generally to relieve symptoms as they arise. There are certain cases, however, in which treatment is of real value, either in arresting the progress of a tumour or in causing its removal. Tubercular masses are often of exceedingly slow growth, and may, in fact, remain quiescent for months or years. If we have reason to suspect the existence of such tumours, it is of course important to have recourse to iron, cod-liver oil, and other drugs and modes of treatment serviceable in tuberculosis. Tumours of syphilitic origin may often, if attacked early, be so far influenced by treatment that

the patient becomes practically restored to health ; and, even if complete restoration be not effected, great and permanent amendment may ensue. Iodide of potassium and mercury are the drugs specially indicated in these cases. The removal of cerebral and spinal tumours has occasionally been successfully performed, and is indicated where symptoms point to their presence in accessible localities.

---

## XI. CEREBRAL AND SPINAL HEMORRHAGE (*Apoplexy*)

*Causation.*—Hemorrhage within the skull or spinal canal is due to various causes. Rupture from violence, as, for example, from blows on the head or spine, or fracture of these parts, may of course occur at any age. Idiopathic hemorrhage, however, although it occasionally arises below the age of twenty, becomes common only after forty ; from which time onwards its frequency in relation to the number of persons living at each successive lustrum rapidly increases. Old age, therefore, has great influence in its causation. It is more common in men than in women. But there are certain other conditions which are of more direct importance than old age or sex. These are, the presence of chronic Bright's disease, and that of degenerative affections of the arterial system, embolism, purpura, hæmophilia, leucocythemia, and idiopathic anæmia.

*Morbid anatomy.*—Hemorrhage may occur either between the dura mater and the bone, within the cavity of the arachnoid, in the subarachnoid space, in the nervous substance, or, lastly, in the ventricles.

1. *Meninges.*—Effusion of blood between the cranium and dura mater is not uncommon in adults, especially as the consequence of blows on the head or fractures of the skull, and is usually immediately referrible to laceration of the middle meningeal artery. The extravasated blood separates the dura mater from the bone in some limited area, and forms a convex protuberance, which displaces the cerebral surface in relation with it. If the patient survive, the blood undergoes those changes which are common to all such extravasations, and, after a while, becomes absorbed. Hemorrhage external to the theca vertebralis is also mostly due to mechanical violence. It may, however, result from the rupture of an aortic aneurysm.

Hemorrhagic accumulation in the cavity of the arachnoid is always referrible to escape of blood either from the dura mater or from the subarachnoid tissue. If the dura mater be its source, it may be either a direct consequence of mechanical violence, or derived from a patch of pachymeningitis, with hemorrhage between its laminae. If the subarachnoid tissue be its source, it may be due to any one of the causes, to be presently discussed, of effusion of blood into that part. The arachnoidean cavity appears to be a frequent seat of effusion of blood in new-born children, probably from violence in the process of being born. Blood escaping into this cavity readily diffuses itself throughout its whole extent. Here, as in other cases, if the patient live, the blood for the most part undergoes

gradual absorption ; occasionally, however, it gets converted after a time into a thin-walled cyst, full of limpid serous fluid, with little or no tendency to undergo further change.

Hemorrhage into the subarachnoid tissue is frequently due to the rupture of an aneurysm of one of the arteries at the base of the brain. It is generally then very abundant, and distends primarily all the lax tissue which abounds in this locality ; encircling the vessels and nerves and concealing them from view, together with the surface of the crura cerebri, pons, and adjoining part of the medulla oblongata ; and extending thence into the laminae of the velum interpositum and the corresponding duplicatures connected with the fourth ventricle, along the fissures of Sylvius, and, according to circumstances, over more or less of the surface of the cerebral hemispheres and lobes of the cerebellum. Sometimes the blood escapes by laceration from a hemorrhagic cavity in the substance of the brain either into the ventricles or on to the surface. This accident is not uncommon in cases of abundant extravasation into either the corpus striatum or the internal capsule ; it is apt also to occur when blood is effused into the pons or crus cerebri. Another cause of subarachnoid hemorrhage is punctiform extravasation, or extravasation from injury to the surface of the brain, as is caused by contre-coup. Subarachnoid hemorrhage is occasionally also observed in connection with the cord.

2. *Brain*.—Hemorrhage into the substance of the brain, especially if it be into certain parts of the cortex, may be due to laceration from violence ; occasionally it results from embolic softening ; but it is a far more common consequence of the rupture of diseased vessels, or of the miliary aneurysms which Charcot and Bouchard have shown to be frequently present, mainly in the optic thalami, corpora striata, cerebral convolutions and pia mater, in cases of cerebral hemorrhage and in old people. The vessels in which rupture takes place are usually the seat of either fatty degeneration, calcareous deposit, or chronic arteritis, with hyperplasia of the corpuscles of the outer wall and perivascular sheath. The minute aneurysms which usually stud them vary, perhaps, from the size of a small pin's head downwards, but occasionally they are as large as a grain of wheat or larger. The escape of blood in some instances, doubtless, is from a single aneurysm or vessel ; but much more frequently it takes place simultaneously from many lacerations occurring within a circumscribed area. In some cases the hemorrhage is mainly from capillaries ; it is then apt to be spotty, and a careful examination will probably reveal in the centre of each spot a capillary vessel, with its lymphatic sheath distended with blood—a capillary dissecting aneurysm, in fact. In other cases, and more especially in those in which the effusion is considerable, and in mass, the presence of miliary aneurysms, and even the ruptured aneurysms, can generally be easily recognised. But here also the rupture is first into the perivascular sheath, so that a dissecting aneurysm precedes the actual escape of blood into the surrounding nervous tissue. The quantity of blood which may be poured out into the brain-substance varies, roughly speaking, from a few minims to several ounces. Groups of minute or capillary

extravasations are occasionally alone present ; and generally, when a large hemorrhagic cavity exists, the tissues around are studded more or less abundantly with similar small hemorrhagic spots. The escaping blood necessarily tears up the brain-substance ; and thus, when its amount is large, a very irregular cavity is produced, the interior of which is occupied by blood mingled with the *débris* of the broken-down nervous tissue, while the margins are formed by the irregular interdigitation of the lacerated brain-substance and of the peripheral portions of the clot.

The extravasted blood speedily coagulates, and, if the post-mortem examination be performed shortly after its effusion, will be found to present the ordinary characters of recent clot. If, however, the patient survive, changes gradually ensue in it and in the brain-substance around. The irregularities of the cavity get smoothed away, its form becomes more rounded, and its margins denser and better defined. The clot contracts, grows drier and more friable, assumes a brownish or rusty tint, and gradually undergoes more or less complete absorption ; the final result being the formation either of a *cicatrix* (which can only happen if the effusion were very small), or, as far more commonly occurs, of a cyst traversed by delicate processes of connective tissue, occupied by a thin serous or milky fluid, and studded as to its parietes with pigmentary particles and crystals of *hæmatoidine*. The time required for the total disappearance of a clot depends upon its size : a small one may be absorbed within a week or two, a large one within six weeks.

The effects of clots on the surrounding brain-tissue must not be omitted. In the first place they always cause displacement and pressure and, if large, flattening of the convolutions, obliteration of the sulci, and displacement of subarachnoid fluid from a greater or less extent of the surface which overlies them. In the second place, the surrounding tissue for some little distance always becomes yellow from imbibition of the colouring matter of the clot, *œdematous*, and softened. In the third place, they are very apt to set up inflammatory mischief in the parts which are in their immediate vicinity. And, lastly, at a later period, descending atrophic changes, which have already been described, are liable to supervene.

Hemorrhage may occur in any part of the brain ; but it takes place mainly in the corpus striatum, and is then generally due to laceration of some of the twigs of a particular branch of the internal carotid, to which Charcot calls special attention, and which we have already referred to. After the corpus striatum, the parts most likely to suffer are the optic thalamus and the white substance of the brain immediately external to these bodies. Hemorrhage occasionally also takes place in the *crus cerebri*, pons, or cerebellum, and, though much more rarely, in the medulla oblongata. Large effusions may implicate the optic thalamus and corpus striatum at the same time, and even destroy these bodies completely. More frequently, perhaps, they involve the corpus striatum and external capsule, and especially, as Dr. Broadbent asserts, the external capsule itself. They are very apt to rupture into the lateral ventricle, or,

if they extend upward, through the cerebral parietes, into the subarachnoid tissue. In the latter case, more or less abundant effusion of blood takes place directly on to the surface of the brain; in the former case, one or both lateral ventricles, or the whole system of ventricles, including the fourth, becomes inundated with blood and sometimes enormously distended, and, in consequence of laceration of the floor of the third ventricle, the effusion may extend over the base of the brain, along the fissures of Sylvius, and even diffuse itself generally throughout the subarachnoid tissue. Dr. Broadbent shows that laceration rarely takes place in the island of Reil or in the course of the Sylvian fissure. Hemorrhage into the pons is not unfrequently continued thence by rupture either into the fourth ventricle or into the subarachnoid tissue below. It is not common for more than one extensive hemorrhage to take place in the brain at one time. But it is by no means uncommon to discover, after death, the remains of one or two or even more extravasations in addition to the recent one which has caused death.

Hemorrhage into the ventricles is almost always secondary to hemorrhage into the brain-substance or to rupture of aneurysms at the base.

3. *Cord*.—Effusion of blood into the substance of the cord is very rare. It depends no doubt in some cases on the laceration of diseased vessels; but in the great majority of cases is probably (as Charcot suggests) secondary to inflammatory softening, and in either case begins in the grey matter. It is said to be more common in youth and middle life, than in old age.

*Symptoms and progress*.—1. *Brain*. The term ‘apoplexy’ is so commonly used to imply cerebral hemorrhage, and is on the whole so misleading when thus used, even if its scope be limited by the prefix ‘sanguineous,’ that it may be well to observe here that typical apoplexy (that condition in which the patient suddenly falls down in complete coma, with total abolition of motion and sensation and of sense, with full pulse, and slow stertorous breathing) is very seldom observed in cases of effusion of blood within the cavity of the cranium. Further, in most works, and especially in those of the older school, much stress is laid upon the type of body which is most liable to apoplexy, on the habits of life which predispose to it, and on the various symptoms which were supposed for weeks, months, or even years, to herald the approach of the actual seizure. It is certain, however, that although there was some amount of truth in the observations which led to these generalisations (a sort of rough connection between the collective antecedents above hinted at and the super-vention at some period or other of death, ushered in with an apoplectic seizure, or due to hemorrhagic effusion), there is little or no direct connection between them and the rupture of a blood-vessel in or on the brain.

In a large number of cases of cerebral hemorrhage the attack comes on suddenly and unexpectedly, although it may be freely admitted that in no inconsiderable proportion of them there has pre-existed, for a longer or shorter time, either chronic Bright’s disease, or some distinct evidence

that degenerative changes have been going on in the arterial system. In other cases there have been precursory symptoms, referrible to local disturbance of the cerebral circulation, caused either by partial obstruction of some artery or by the occurrence of capillary bleeding, or it may be by the actual formation of a hemorrhagic cavity which, either from its smallness or from its situation, is unattended with striking symptoms or permanent injury. Among the symptoms here adverted to may be enumerated headache, vertigo, confusion of thought, failure of memory, drowsiness, want of sleep, irritability of temper, and the like. Others are bleeding from the nose and retinal hemorrhage. But the most important are temporary paralytic phenomena, such as numbness or tingling on one side of the body or in the arm or leg, loss of power in the same parts, or in one half of the tongue or face, difficulty of articulation or deglutition, and double vision. It must not, however, be assumed that any of these symptoms necessarily points to the occurrence of hemorrhage. They may equally indicate the presence of a tumour, or other circumscribed lesion, or be connected with epilepsy or other purely functional affections of the brain.

The symptoms which attend effusion of blood into the brain are very various both in kind and in severity. Sometimes the patient, while engaged in his ordinary avocations, suddenly finds that he has lost the use of his arm, and presently becomes hemiplegic; sometimes, while engaged in conversation, his articulation becomes thick, and he presently discovers that his mouth is drawn to one side, and that an arm and leg are limp and weak; sometimes the first intimation that there is anything amiss is the accidental discovery by the patient that one side of his body is totally useless when he attempts to rise from his bed in the morning, or from a chair in which he has been sitting quietly or dozing. In other cases the appearance of paralysis is attended or preceded by sudden giddiness or confusion of thought, or by a pain or sensation in the head which makes the patient cry out. In some instances he talks and acts for a few seconds like a drunken man. In some he suddenly becomes faint and collapsed, with pallid face, cold damp skin, feeble irregular pulse, and vomiting—the affection is ushered in indeed with an attack of syncope, during which he may become insensible, but from which he often recovers, to lapse, after a longer or shorter time, but gradually, into coma and paralysis. Here Dr. Broadbent believes that the hemorrhage begins in the external capsule. In exceptional cases only does the patient become at once comatose; and then the attack is apt to commence with a convulsion. The last are for the most part cases in which blood is effused into the pons Varolii, or on to the surface of the brain from rupture of a large vessel or aneurysm. When the patient becomes suddenly faint, or comatose, there is usually a fall of temperature, which is sometimes considerable, and may last some hours.

The further progress of the disease presents the greatest variety. In some instances the patient's symptoms stop short at that indistinctness of speech or that unilateral paresis with which he was seized; and he remains in this condition for a few hours, a few days, or a few weeks. In some

instances these primary symptoms become aggravated up to the super-vention of absolute hemiplegia, with or without anæsthesia; in which condition again the patient may remain for a variable time, sometimes recovering completely sooner or later, sometimes undergoing imperfect recovery, and remaining more or less feeble on the affected side, or in some degree inarticulate, for the remainder of his life. Not unfrequently headache, vertigo, impairment of intellect, or alteration of temper, not only is present during the continuance of the paralysis, but persists even after its amelioration or disappearance. Occasionally there is temporary deviation of the eyes, and even of the head and neck, towards the unparalysed side. In many instances coma presently succeeds the symptoms of invasion. This may come on in the course of a few minutes, a few hours, or a few days, even in those cases in which the initial symptoms are of the mildest character. It generally supervenes before long in those whose first symptoms are those of shock: the patient recovers from his faintness, perhaps to find himself hemiplegic, not improbably to feel fairly well; but by degrees drowsiness and stupor creep on and gradually deepen into profound coma.

But, however the coma may come on, whether it be gradual in its invasion, whether it supervene in the course of symptoms already pointing to cerebral hemorrhage, or whether it becomes developed in all its intensity within a few minutes or a quarter of an hour of the first signs of illness, its symptoms do not on that account present any differences. The patient lies on his back insensible, with face flushed, skin moist, pulse slow, perhaps irregular, but full and hard, respirations slow and attended with stertor or snoring as he draws his breath in, and puffing of the cheeks as he exhales. In the early condition of this, which is sometimes termed the apoplectic state, the patient is still perhaps capable of being roused; when spoken to loudly he makes some incoherent response; when pinched or pushed he indicates by some movement or gesture that he is not altogether without feeling. But soon he becomes utterly unconscious. In this condition many various symptoms cluster, as it were, around his unconsciousness. In some cases he lies on his back quietly as if asleep, his expression placid, his limbs apparently unaffected assuming a natural attitude. But usually there is obvious muscular affection: the limbs of one or both sides are flaccid—when raised falling back helplessly on the bed; or they are rigid, and offer more or less resistance to the attempts to move them; or convulsive twitches or more powerful spasmodic movements occur from time to time either generally or on one side of the body. There may, in fact, be simply that failure of the muscles to move which stupor alone involves, or there may be general or unilateral paralysis with or without flaccidity, rigidity, or convulsive movements. In the face the same conditions may be observed: sometimes the muscles are in repose; sometimes more or less obvious facial palsy is observed upon one side, sometimes twitching of the muscles. The eyelids are generally shut. The condition of the eyes varies: frequently the pupils are dilated, especially towards the fatal close; sometimes, and more especially in cases of

hemorrhage into the pons, they are contracted ; often they are natural ; they are sometimes irregular, sometimes insensible to light. The last are symptoms of considerable significance. In the early stage the patient, though unable to masticate, is still able to swallow fluid or food placed in the back of his mouth ; when, however, the case is going on unfavourably, the power of deglutition fails absolutely. Respiration, as has been stated, is usually slow, but it is often irregular, and is liable to cease completely for some seconds. The Cheyne-Stokes character is often well marked. Sometimes the patient breathes as quietly as a child. But when a fatal termination is impending, stertor (if it were not before present) comes on ; mucus and other fluids accumulate at the back of the throat and in the air-passages ; the breathing becomes attended with loud rattling sounds, and the respiratory movements are often accelerated.<sup>1</sup> The character of the pulse varies : at first probably it is slow, full, and hard, but it may be of natural rate, and present no deviation whatever from the normal ; but with the continuance of coma it is apt to increase in frequency, and may rise to 120, 140, or 160 in the minute. The face usually is flushed, the skin moist ; and towards the end of life profuse sweats generally, if not always, break out. The patient has retention of urine, and loss of control over his alvine evacuations. Inability to swallow, accumulation of fluids in the fauces and air-passages, indifference of the pupils to light, failure of the eyelids to close when touched, extreme rapidity of pulse, and the occurrence of profuse perspirations are phenomena of the gravest omen.

In some cases the stupor of coma passes in the course of a few minutes, a few hours, or a few days, into that of death. But in a considerable number of cases the patient, after a longer or shorter time, slowly emerges from it, regains his consciousness more or less completely, and probably is found to be paralysed on one side, and to present a greater or less number of other indications of cerebral mischief. From this point, sometimes recovery is rapid and thorough ; sometimes hemiplegia continues for a considerable period, or, after more or less improvement, for life ; sometimes he has hemianæsthesia as well as paralysis ; sometimes his speech remains indistinct or his voice feeble ; sometimes he has aphasia ; sometimes he complains of headache or giddiness ; sometimes he has loss of memory, failure of intelligence, or emotional perversion ; or he may be stupid or demented, and then not unfrequently fails to control his bowels

<sup>1</sup> Dr. Bowles, who has given much attention to the subject of the stertor which attends apoplectic and other forms of coma, describes a nasal stertor due to paresis of the muscles of the external nares, a palatine stertor characterised by vibration of the soft palate, a pharyngeal stertor resulting from narrowing of the interval between the back of the tongue and posterior wall of the pharynx, and a stertor referrible to the larynx and air-passages below the larynx ; and he draws attention to the dangers which attend some of the forms of stertor, and points out how they are to be counteracted. The most dangerous of them are pharyngeal stertor, which may generally be relieved by shifting the patient's position, and especially by laying him on his side ; and stertor referrible to the air-passages, attended with accumulation of mucus therein, which also may often be benefited by change of posture.

or his bladder. It is obvious that the various conditions here described are in the main identical with those which are apt to follow hemiplegia coming on without insensibility; and that, in fact, but for the circumstances that the supervention of coma on the whole implies either a large effusion of blood, or effusion into some vital part, and that coma itself brings with it special dangers, there is no essential difference as regards their subsequent progress between those cases of cerebral hemorrhage which are attended with coma and those which are and have been free from coma.

The character of the symptoms will be determined largely by the seat of lesion, by the size of the clot, and by the rapidity with which the blood is effused. When hemorrhage occurs in the corpus striatum, or in the white matter or convolutions of the brain in relation with the motor tract, or in the crus cerebri, motor hemiplegia will almost necessarily follow, and will probably be more complete according as the amount of brain-substance destroyed or compressed is larger. If, however, the effusion take place in the white matter of the hemisphere, paralysis is more likely to be absent than if it occur lower down; if it take place in the crus, it is probable that the third or fourth or some other of the nerves on the same side as the clot will also be implicated. Aphasia generally attends right-sided paralysis. Hemianæsthesia alone is rarely if ever present; but it is not unfrequently associated with hemiplegia, especially perhaps with hemiplegia of the left side; in which case the hemorrhage probably involves the optic thalamus, internal capsule, or crus. We have previously drawn attention to the fact that sudden but temporary loss of sight on the anæsthetic side is occasionally observed. If blood primarily effused into the corpus striatum or other neighbouring parts escape with sudden violence into the ventricular cavities and flood them, the pressure which is at once exerted on a large number of ganglia essential to life induces sudden profound coma with general paralysis and flaccidity of the limbs. Also, if the surface of the brain be suddenly deluged with blood, profound coma almost immediately ensues, which is often attended with convulsions, but by no means necessarily with paralysis, and in some cases, especially if it be at the base, with inequality of pupils. When hemorrhage occurs in the pons, there are often convulsions, and usually sudden profound coma and general paralysis, attended at the commencement with contraction of pupils; and the case is rapidly fatal. Sometimes, however, the effusion here is small in amount and unsymmetrical in position, in which case the paralytic symptoms will probably be irregularly distributed; there will perhaps be hemiplegia, with implication of various sensory and motor nerves, situated either on the side opposite to the hemiplegia, or irregularly on both sides; there is apt also to be serious interference with the muscles of speech and deglutition—the usual symptoms, in fact, of bulbar paralysis. Hemorrhage into the cerebellum is often attended with severe occipital pain, vomiting, and especially vertigo. Paralysis is for the most part absent, but the patient, if able to walk, staggers like a tipsy man.

After the initial fall of temperature (to which attention has already been drawn) which sometimes lasts for a few hours, there is usually a rise which in grave cases may reach  $105^{\circ}$  or more. Occasionally the temperature rises from the very beginning of the attack: and especially this appears to be the case when the seat of hemorrhage is the pons or medulla.

We have already pointed out that a patient who has had cerebral hemorrhage, whether he has had coma from which he has emerged, or whether he has had a simple attack of paralysis and has attained that stage at which all present fear of coma has passed away, may rapidly or slowly recover from all his symptoms, may recover imperfectly, or may remain without any improvement whatever. We have not, however, referred to the important fact that various complications may arise in the progress of the case. The principal of these may be briefly considered. *a.* The presence of a clot, and of the collateral œdema which always attends its presence, is very apt to induce, at any time during the first few weeks after its formation, some inflammation in the surrounding brain-tissue—an occurrence which is often indicated by elevation of temperature, rapidity of pulse, return of paralysis, drowsiness, and impairment or loss of control over the emunctories, and may lead to coma and death. *b.* Bed-sores are apt to form. In some instances these come on when the patient is bedridden, or has continued for some length of time in a fatuous or semi-comatose condition just as they may come on in any other persons who are confined to bed and of uncleanly habits. But they are also apt to appear, and then mainly upon the buttock of the paralysed side, from the second to the fourth day after the attack, apparently in consequence of some direct influence transmitted from the seat of lesion in the brain. The formation of these early bed-sores is always a bad sign, and almost without exception foretells an early fatal issue. *c.* Inflammation of internal organs, such as pneumonia, dysenteric ulceration, and the like, occasionally supervenes. *d.* Not unfrequently, after the second or third week, or later, if the limbs remain paralysed, rigidity and contraction gradually ensue, associated after a while, in some cases, with wasting of the muscles. This rigidity is not to be confounded with the temporary irritative rigidity sometimes observed at the commencement of paralysis, but is the consequence of secondary degenerative changes in the course of the lateral columns of the spinal cord, and is permanent. It is observed by Trousseau that in those rare cases of hemiplegia in which the arm recovers more rapidly than the leg, the prospects of the patient are very gloomy; that the leg becomes stiff and painful; that imbecility comes on, and the patient usually dies within the year. Whatever the explanation of the imbecility in these cases may be, it seems pretty certain that the arrested recovery of the leg is sometimes due to the fact that degenerative disease has already commenced in the cord. *e.* All patients who have had one attack of cerebral hemorrhage due to disease of the cerebral vessels are specially likely to have subsequent attacks; and sometimes two or three of these occur at irregular intervals, previous to the fatal issue of the case, adding complexity to the patient's symptoms. Lastly, partly from

the effect of the primary lesion, partly from the associated diseased state of arteries, partly from pressure, œdema, inflammation, or degeneration of surrounding parts, many additional symptoms are liable to come on—among others athetosis, choreic movements, epileptiform attacks, delirium, mania, and dementia.

2. *Cord*.—Hemorrhage into the arachnoid cavity or subarachnoid tissue or into the substance of the cord is so rare, except as a consequence of injury or pre-existing disease which has already caused serious symptoms referrible to the cord, that it is scarcely necessary to discuss at length the symptomatology of these lesions. It is sufficient to say, that meningeal hemorrhage is likely to cause sudden pain at the seat of escape or along the spine and in the course of such sensory nerves as become compressed, spasm or rigidity of the muscles of the back and of muscles supplied by the involved motor nerves, and finally perhaps more or less well-marked paralytic symptoms; and that hemorrhage into the substance of the cord is attended with precisely those symptoms which occur in inflammatory softening involving the whole thickness of the cord, the main distinction being that hemorrhagic paraplegia is more sudden in its onset, and more immediately complete, than the paraplegia of inflammation. Its occurrence is often attended with pain. In both cases the symptoms will vary according to the seat of effusion, its extent, and the degree of pressure or damage occasioned by it; and in both the onset of the attack is occasionally attended with loss of consciousness.

*Treatment*.—When a patient is seized with sudden paralytic symptoms due, as we suppose, to hemorrhage, there is little to be done save to keep him perfectly quiet, mentally and bodily, to make him lie down with his head somewhat elevated, in a room of equable but not elevated temperature, and to feed him sparingly with milk and farinaceous food. There is no harm, probably, even if there is no good, in giving him cooling drinks, and in administering medicines which are supposed to check hemorrhage. A powerful purgative is often given, but it is questionable whether the straining which attends its action is not more injurious to the patient than the retention of fecal matter in the bowels. Nevertheless it is desirable that the bowels be moved by some mild but efficient purge. If coma have come on, again there is little to be done beyond leaving the patient at rest. Some bleed, but bleeding will not benefit those who have large effusions of blood in the pons or ventricles, or on the surface; and those who have large hemorrhages elsewhere for the most part recover from their coma without any such assistance. Further, bleeding is probably quite incompetent to arrest cerebral hemorrhage. Nevertheless, we are inclined to believe that the guarded removal of blood in these cases may sometimes prove beneficial, by diminishing pressure within the skull, or, as Sir Thomas Watson suggests, by relieving the congestion of the right side of the heart, which is often manifested by engorgement of the veins of the head and neck, and lividity of surface. At all events, a single bleeding will probably have no injurious effect whatever. It is customary to give powerful purgatives in these cases, such as a couple of drops of croton oil alone, or mixed with a

little castor oil ; and on the whole the practice appears to be good ; purgation tends to derive (as the expression is) from the head ; and in cases of profound coma does not induce that powerful straining which is so great an objection to its employment when the patient is sensible. Other measures which may be adopted are the application of cold in the form of evaporating lotions or ice to the shaven head, or of counter-irritants, such as mustard plaisters, to the head, back of neck, and legs. During the further progress of paralysis following hemorrhage, the chief things to do are still to keep the patient quiet, and free from either mental or bodily excitement, to regulate his hours and employments, to keep his bowels regular, if necessary by the use of opening medicines, to relieve all discomforts and secondary affections under which he may happen to labour, to counteract, as far as possible, the effects of any renal or other organic disease of which he is the subject, and to attend very carefully to his diet. As a rule, all alcoholic beverages should be interdicted, or, if circumstances render their use necessary, should be allowed only in small quantities, and in a dilute form. The patient should be well nourished, but the amount of food given him should not exceed what is essential for his well-being. The food, moreover, should be wholesome and readily digestible. It is often recommended that the patient should be restricted to a vegetable diet and milk—a diet which is doubtless very appropriate if there be any chronic renal affection. But if his abdominal viscera be healthy, we do not see how such diet should have any superiority over a diet containing a fair proportion of animal food. As regards the affected limbs, friction and faradism are sometimes efficacious, when the acute symptoms have passed away, in promoting the restoration of the impaired motor powers ; and when late contraction is occurring it may be relieved or prevented by galvanising the contracting muscles and faradising their opponents.

## XII. OBSTRUCTION OF CEREBRAL ARTERIES

(*Thrombosis. Embolism. Softening*)

*Causation and morbid anatomy.*—We have drawn attention to the facts : that the group of arteries supplying the brain, although anastomosing freely in the circle of Willis, have no further communication with one another excepting by means of the capillary vessels situated at the periphery of their several areas of distribution ; that the same arrangement holds good with respect to every branch of these arteries, down to their smallest twigs ; and that hence any obstruction however produced, whether in a primary or in a subordinate branch, no matter how small, puts a stop to the circulation of the blood in the district to which the obstructed vessel leads, and involves its degeneration and death. The same rule obviously does not apply with equal force when obstruction takes place in the basilar or either internal carotid artery below the anastomosis, since by means of that anastomosis blood for the most part finds

its way readily from the pervious trunks to the branches of the obstructed vessel. Nevertheless, such obstruction, or even obstruction of the common or internal carotid in the neck, occasionally influences seriously the nutrition of that portion of the brain with which the obstructed vessel is in relation. The arteries of the cord, on the other hand, are small, are derived or reinforced from many sources, and rarely, so far as we know, become obstructed, or if obstructed, instrumental in the production of degenerative changes in the substance of the cord.

The causes of obstruction are various. *a.* In many cases the arteries at the base of the brain in persons advanced in life get rigid, thick-walled, and the seat of atheromatous or calcareous degeneration; and as a consequence of the advance of these processes it sometimes happens that one of the diseased vessels becomes reduced in calibre or altogether impervious. *b.* In a considerable number of cases, again, one of the arteries at the base of the brain or one of the primary branches becomes obstructed in a greater or lesser portion of its length by a clot or thrombus, which fills it, adheres to its surface, and after a while undergoes degenerative changes, in which also the vascular parietes probably share. The causes of such thrombosis are not always obvious. Occasionally it is due to the fact that the affected vessel leads to some diseased tract in which the smaller vessels are involved and obstructed; and the coagulation of blood in it is therefore secondary. Sometimes, possibly, it is due to the special tendency which the blood appears to have in some dyscrasic conditions to undergo spontaneous coagulation. Frequently it is determined by disease of the arterial walls, such as roughening from atheromatous or other chronic processes, inflammatory thickening, or especially syphilitic arteritis. *c.* But perhaps the most interesting cause of obstruction is the detachment of granulations from diseased valves on the left side of the heart, their conveyance to the arteries of the brain, and their impaction, usually at the point of bifurcation of an artery, or at some other spot where the vessel is too small to allow of their further transmission. The embolus usually forms the nucleus for the development of a thrombus extending to a greater or less distance in either direction along the channel of the obstructed artery.

Obstruction of the arteries at the base from atheromatous or earthy degeneration is observed mainly in persons advanced in life, and especially in those suffering from arterial disease elsewhere, or who are the subjects of chronic renal disease, or have led laborious or debauched lives. The obstruction usually occurs in one of the arteries forming the circle of Willis, or in one of the trunk-vessels below this anastomosis.

Thrombosis is not uncommon in the vertebrals, the basilar, the internal carotids, and their several primary branches; and indeed not very infrequently involves two or three of these vessels, one after the other, at regular intervals. Obstruction from thrombosis connected with arterial degeneration is an affection of advanced life; as a consequence of syphilis, it is mainly a phenomenon of early adult life and middle age.

Embolism is in the great majority of cases the consequence of rheu-

matic inflammation of the valves of the heart ;<sup>1</sup> it may, however, follow degenerative lesions of the same parts and the detachment of masses of calcareous or atheromatous matter, or of fibrinous tubercles which have become developed on the degenerate surfaces. Embolism may occur at almost any period of life, yet is certainly most common from puberty up to the age of forty or fifty. It almost always affects the middle cerebral artery in some part of its course, and usually the middle cerebral of the left side.

The changes in the brain-substance which result from arterial obstruction are (excepting when this takes place below or in the circle of Willis) almost accurately limited to the district which the obstructed vessel supplies. The affected region becomes opaque white, yellowish, or greenish, mottled with light red patches, or even minute extravasations of blood, and softened—often so soft as to break down readily into a pulp under the finger, or to admit of being washed away under the impulse of a stream of water. The microscopic characters which it presents depend on the appearance of granule-cells in greater or less abundance, on the degeneration of the nervous elements, more especially the white substance of Schwann, and its conversion into masses of refractive globules, and on the accumulation in the walls of the vessels and perivascular sheaths of numerous fatty granules. Patches of softening from obstruction, especially if of small size, may, like apoplectic clots, become absorbed, and leave behind them a mere scar or a cavity containing serous or milky fluid. If of large size, they may undergo more or less diminution of bulk, and involve obvious shrinking of the mass of brain in which they are contained. Not unfrequently inflammatory changes go on in the brain-substance around them. Occasionally abundant hemorrhage, like that of ordinary sanguineous apoplexy, results from the softening consequent on arterial obstruction.

*Symptoms and progress.*—The symptoms due to obstruction of one of the cerebral arteries so closely resemble those caused by hemorrhage that, if there be no appeal to other facts than those afforded by the cerebral symptoms which are present, it is utterly impossible in the great majority of cases to distinguish the one affection from the other. It is stated by Recamier and by Todd, and their views are supported by Trousseau and many others, that whenever hemiplegia, complete and absolute, occurs suddenly without loss of consciousness, it is due to softening and not to hemorrhage. And in reference to this statement, we may point out that the mere sudden loss of function in a limited portion of brain-tissue (as occurs in softening) is likely to be attended with less general disturbance of the cerebral functions than the extravasation of blood into a similarly

<sup>1</sup> It is a curious fact that, within a few weeks of one another, two cases occurred to Dr. T. Barlow, and one to ourselves, in which children convalescent from scarlatinal nephritis with dropsy, who had not had rheumatism and had no signs of valve-disease, were attacked with hemiplegia, in one case associated with blindness of the eye on the non-paralysed side. There is little doubt that these were cases of embolism dependent on detachment of vegetations from the auricular aspect of the mitral valve.

limited space, which not only destroys the tissues which it infiltrates, but, from its bulk, causes more or less serious pressure on surrounding parts. The rule may doubtless, within certain limits, be accepted as the expression of a fact ; but it is a rule to which there are frequent exceptions ; for in many cases of softening from arterial obstruction, the hemiplegia, if sudden, is not complete, and in some the attack is ushered in by loss of consciousness ; while on the other hand, hemorrhagic hemiplegia, as we know, is in a large number of cases unattended with insensibility.

Various prodromal symptoms of cerebral softening are often enumerated ; but it is clear that in most of the varieties of softening now under consideration no symptoms of the kind are likely to be met with. They can attend neither embolism nor thrombosis. And any that may be referred to disease of the arterial walls are equally indicative of future hemorrhagic effusion. As a matter of fact the symptoms due to arterial obstruction are always sudden in their onset, and for the most part occur unexpectedly at a time when perhaps the patient seems to be in perfect health. The seizure comes on in various ways : sometimes the patient, who is walking or making some exertion, or perhaps even sitting down quietly, is attacked with sudden vertigo and confusion of thought, and tumbles or throws himself forward on the ground ; sometimes he is seized with sudden pain in the head of such severity that he cries out ; sometimes he suddenly becomes faint, and occasionally this faintness is attended with a slight convulsion. But, however various these initial symptoms, it is almost always discovered so soon as the momentary attack has passed that hemiplegia is present. It is almost needless to say that the character of the symptoms which present themselves and their severity must depend largely upon the size of the vessel obstructed and the part to which it is distributed—in other words (as also in hemorrhage), on the amount of brain-substance which becomes incapacitated, and on its situation. Thus affections of the posterior cerebral lobes and of the cerebellum are always more obscure in their symptoms than those which involve the anterior parts of the brain, and more especially than those which involve its base. And hence obstructions arising in the course of the posterior cerebral and cerebellar arteries lead to less definite, if not less serious, consequences than obstructions in the course of the anterior and middle cerebrals. It is very important, however, for the purposes of diagnosis to refer to the exact distribution of the various intracranial vessels which has been given on a former page. And especially is it important to bear in mind : that it is from the basilar artery that the pons mainly receives its vascular supply ; that the posterior cerebral artery is distributed not only to the posterior part of the cerebrum, but especially to the posterior part of the optic thalamus, and to the corpora geniculata and quadrigemina ; and that in the great majority of cases, and certainly in almost all cases of embolism, the obstruction occurs in the middle cerebral artery or in one of its branches, and that the tract which then undergoes softening is the district to which this vessel is distributed, or some part of that district, which includes the greater portion of the corpus striatum, the

internal capsule, the anterior half of the optic thalamus, and nearly the whole of the antero-lateral region of the brain, inclusive of the island of Reil and the convolutions which surround the fissure of Sylvius. It is hence obvious, in the case of embolism: that the main symptom which the patient would be expected to present is more or less complete (generally complete) hemiplegia, not improbably associated with some degree of anæsthesia, and impairment of intelligence; and that if the disease occupy the left side of the brain, either marked aphasia, or total inability to utter articulate sounds, will be present. Other symptoms, however, which are not special to softening, are generally associated with these—namely, vertigo, headache, sickness, rigidity of the affected limbs, loss of control over the bladder and rectum, and the like. Occasionally the attack of hemiplegia is attended with sudden loss or impairment of sight on the same side as the cerebral lesion, a phenomenon apparently dependent on the concurrent plugging by embolism or thrombosis of the orbital artery or *arteria centralis retinæ* and of the middle cerebral, or on common obstruction of the internal carotid and its branches.

The subsequent progress of cases of obstructed cerebral arteries depends largely upon the extent of softening and its situation. If the patch be small (even if it be in the distribution of the middle cerebral) recovery as complete as occurs after some cases of effusion of blood may be expected. In most cases, however, recovery does not take place; in some the patient improves up to a certain point; in some he remains, so far as his mental and motor failures are concerned, much as he was immediately after his seizure. Occasionally, and especially if the case be one of thrombosis and not of embolism, several of the cerebral arteries, and even the main trunks of these vessels, may be obliterated at successive intervals, each attack adding its own special symptoms to those which had resulted from previous lesions. It remains a fact, however: that the patient rarely recovers completely from the effects of thrombotic or embolic softening; that if he has become aphasic, the aphasia continues in a greater or less degree; that hemiplegia for the most part persists, and is followed ere long by that form of contracture which results from secondary lesion of one of the lateral columns of the cord; and that occasionally arthritic effusion or inflammation ensues, or wasting of muscles. Further, the intellect, already probably impaired, is apt to fail, and the patient after a while to become bedridden and childish. Bed-sores occasionally form rapidly after softening, as they do after hemorrhage; and inflammatory processes may go on around the softened patch and bring with them special symptoms. It follows on the whole that the prognosis in cases of softening is very unsatisfactory, and that even if patients survive they are apt to survive in a more or less maimed or wrecked condition. On the other hand, we have notes of the case of a young woman suffering from the effects of rheumatic endocarditis, who was attacked suddenly with right hemiplegia and aphasia, apparently due to embolism, yet recovered absolutely in the course of a few hours. Two or three months later she unfortunately had a second attack, from which, as usual, permanent paralysis resulted.

Death may occur at any period. Sometimes it comes on early, the patient dying from coma, bed-sores, or failure of nutrition, or from pneumonia, or some other such complication. Death at a later period may be consequent on the recurrence of apoplectic attacks or on the supervention of inflammation around the focus of disease; or it may be due to asthenia or inter-current disorders.

There is for the most part extreme difficulty in determining of any case which comes before us whether it be one of sanguineous effusion or one of softening from arterial obstruction. In many cases, indeed, there is nothing whatever to aid us in coming to a differential diagnosis. The chief points on which reliance must be placed are the following:—First, our knowledge of the relative seats of hemorrhage and of softening and of the different symptoms which they are hence likely to evoke. Second, the clinical history of the patient and the state of his various organs: thus the case is likely to be one of embolism if there be heart-disease present, or if there be a history of his having had former cardiac mischief, or even if he have had an attack of acute rheumatism or scarlet fever; it is not unlikely to be one of thrombosis if the patient have had a chancre, or if he be suffering, or present traces of having suffered, from the secondary or later symptoms of syphilis; it is almost certain to be hemorrhagic if we discover the presence of albuminuria or chronic renal disease, arterial degeneration, or hemorrhage into the retinae. And, third, the age of the patient—cerebral hemorrhage being on the whole a disease of advanced life, embolism occurring indifferently at all ages from puberty upwards. We need scarcely repeat that the occurrence of sudden and complete hemiplegia without loss of consciousness and without premonitory symptoms points strongly to arterial plugging, while the gradual development of symptoms culminating in hemiplegia and coma is strikingly characteristic of cerebral hemorrhage.

*Treatment.*—It is needless to lay down any specific rules of treatment. We cannot reopen an obstructed artery; we cannot hope that the district to which it leads shall be fed by collateral channels. The softened part remains necrosed, and the best thing that can happen is that it shall shrink into an inert mass or undergo absorption. It may, however, during this process induce inflammatory mischief in the parts around. This contingency should be guarded against as much as possible. For which and various other reasons the patient should be kept quiet and cleanly, his bowels should not be allowed to become constipated, and his food should be nutritious, but easy of digestion, and not too abundant. But, indeed, the same general treatment is applicable to these cases as to cases of paralysis after hemorrhage, and need not be more particularly considered.

---

## XIII. HYDROCEPHALUS AND HYDRORRHACHIS

*(Cerebral and Spinal Dropsy)*

*Causation and morbid anatomy.*—Dropsical accumulations in the cavities connected with the brain and cord are not uncommon, their chief seats being the subarachnoid space and the ventricles. A relative excess of subarachnoid fluid, which has been mistaken for dropsy, is generally observed in connection with the shrunken brains of old persons and of those who die demented or fatuous, or the victims of certain other chronic forms of insanity. Whenever any portion of the brain, whether from congenital defect or as a consequence of disease, wastes, the space which it formerly filled becomes occupied either by an excess of subarachnoid fluid or by fluid accumulated in a local dilatation of one of the ventricles. Further, effusion of serum attends the progress of many morbid conditions, such as inflammation, morbid growth, and softening: thus, in some cases of meningeal inflammation, inflammatory products with excess of fluid accumulate in the subarachnoid space; in some cases the substance of the brain becomes wetter or more succulent than natural, or serous infiltration (collateral oedema) occurs in the vicinity of foci of disease; and in some cases (and these are the most frequent and important) the lateral ventricles, the third ventricle, or the fourth ventricle, or all of them together, get largely distended with fluid. In the last series of cases the accumulation of fluid in one situation is balanced by its removal from other situations; and hence, as a rule, excess of fluid on the surface is attended with comparative absence of fluid from the ventricles: and dropsy of the ventricles or substance of the brain causes flattening of the convolutions, obliteration of the sulci, and dryness of the subarachnoid tissue. Dropsical effusion plays an important part in the production of symptoms in the cases which it complicates; but by far the most important, in this respect, is the intra-ventricular dropsy, which is so commonly associated with the presence of tubercles or other tumours of the brain, or of meningeal inflammation, and which occasionally arises (both in children and in adults) as an independent malady. This is often referred either to compression or obstruction of the *venæ Galeni*, or to closure of the natural communications existing between the ventricles and the subarachnoid tissue.

The most important and striking forms of dropsy are congenital, or come on without obvious cause shortly after birth, sometimes associated with malformation, sometimes independently of it.

1. Among the former of these classes must be included: in connection with the brain, hydromeningocele and hydrancephalocele; in connection with the cord, spina bifida.

a. In *hydromeningocele* and *hydrancephalocele* a congenital perforation is present, either in the occipital bone (which is most common), or in some other part of the vault of the cranium; through which protrudes, in the form of a tumour, either the membranes of the brain alone, with a cir-

cumscribed accumulation of serum (hydromeningocele), or a portion of brain nipped off, as it were, from the rest, and usually containing within it a dilated dropsical diverticulum from one of the ventricles (hydrencephalocele).

*b. Spina bifida* generally occurs in the sacral or lumbo-sacral region, but may be met with in the neck or any other part of the spine. It forms a rounded tumour, usually with a central dimple, and is due partly to the fact that the arches of the vertebræ in the situation of the tumour have remained ununited, and partly to the fact that the membranes of the cord are there expanded and distended with dropsical fluid, and protrude through the abnormal fissure. In some instances the membranes alone protrude, and we have then a condition which is equivalent to hydromeningocele. But much more commonly (especially if the disease be at the lower end of the spinal canal) the cauda equina is prolonged into the cavity. The filum terminale is then attached to the centre of the concavity of the cyst, causing the dimple to which reference has been made; and the nerves of the cauda equina accompanying this to the posterior aspect then arch forwards across the cavity—double upon themselves—to reach their several foramina. If (as sometimes happens in such cases) the central canal of the implicated portion of the spinal marrow be dilated into a cyst, we have a condition which is the exact counterpart of hydrencephalocele.

2. Congenital or early developed dropsy (independent of malformation) probably always occupies the ventricles; although in some cases, apparently by accident, fluid becomes effused also into the cavity of the arachnoid.

*a. Chronic hydrocephalus* (as it is generally called) sometimes commences during the later period of intra-uterine life, and the child is born already hydrocephalic. More frequently, however, the first manifestation of the disease occurs between the time of birth and six months after that event. But it may come on at any time previous to the union of the cranial sutures; and a few cases are recorded in which the supervention of dropsy shortly after this union has caused the bones again to separate. The fluid of hydrocephalus is of higher specific gravity than cerebrospinal fluid, and contains albumen, chloride of sodium, and urea. It mostly occupies the lateral, third, and fourth ventricles; and its gradual accumulation leads to their dilatation, to the flattening of the various projecting ganglia, to the rounding of the several cavities, and to the enlargement of their orifices of communication. In this way the lateral ventricles may become enormously dilated, the side walls of the third ventricle may be opened outwards, until they become horizontal, and lost, as it were, in the common floor of the general ventricular cavity, and the foramen of Monro and the fissure passing thence backwards beneath the fornix may be so much dilated as to form a free arch-like communication (of which the surface of the expanded third ventricle forms the floor) between the two lateral ventricles. The dilatation is not, however, always uniform or general. In some cases one lateral ventricle is much more enlarged than its fellow, or one part of a ventricle much more expanded than another part. In some cases, indeed, the posterior cornu becomes isolated from the rest of the cavity, and forms an independent

cyst. Sometimes the third or fourth ventricle remains unaffected ; sometimes the dropsy is confined to one of these cavities.

The effect of the gradual distension of the lateral ventricles upon the cerebrum is remarkable. We have pointed out that the various elevations and depressions in the ventricular walls become effaced, and that the lateral ventricles tend to communicate freely with one another in consequence of the displacement upwards of the corpus callosum, septum lucidum, and fornix. Concurrently with these changes the convolutions on the surface of the organ become unfolded, until finally, in extreme cases, their grey matter forms a continuous smooth plain over the dilated hemispheres, which at the same time become reduced in thickness to a half or quarter of an inch, and, in some situations, probably to that of writing paper. Under these circumstances the dilated ventricles not unfrequently contain several pints of fluid ; indeed, cases are quoted by Trousseau in which 30, and even 50 lbs. were found in them. Occasionally, as in the well-known case of the man Cardinal reported by Dr. Bright, rupture of the surface of the brain or of its meninges occurs in the course of the disease, so that the fluid originally contained in the ventricles accumulates in the cavity of the arachnoid, and the brain lies collapsed and empty on the floor of the skull.

The effects of hydrocephalus on the skull, on the nervous functions, and on the development of the child, are very important. As the dropsy increases, the head gradually enlarges, mainly in its lateral and upper parts ; the two halves of the frontal bone, the parietal bones, and the occipital bone open (as Trousseau expresses it) like the petals of a flower, and are thrown outwards, while the intervals between them become proportionately widened. Consequently the forehead, the sides of the skull, and the occipital region all protrude, while the head becomes somewhat flattened at the top. At the same time, some want of symmetry is usually apparent. The inordinate size and strange shape of the skull impart to the comparatively small face below it a peculiar aspect, which is aggravated partly by the emaciation which is usually present, and partly by the influence of the enlarging skull on the eyelids and orbits. The upper walls of these cavities are displaced downwards by the pressure to which they are subjected from above, while the upper eyelids, with the eyebrows, are drawn upwards over the forehead by the tension of the stretched pericranial integuments. The eyes consequently become prominent, and present a peculiar staring character, due to the fact that the sclerotic coat is habitually visible above the upper margin of the cornea.

The integuments of the head become attenuated and tense, the superficial veins remarkably distinct, and the hair scanty and poor. The displaced bones also become thin, and the serrations of their edges irregular and straggling. Further, as the case progresses, nuclei of ossification appear irregularly in the tense membrane which intervenes between the separated bones, and these grow into irregular osseous plates, termed ossa triquetra. After a time, with the aid of these intercalated bones, the sutures and fontanelles may become entirely closed. This closure, how-

ever, may not take place for twenty years or more. The patient almost always emaciates notwithstanding that his appetite may continue good: the frame remains undeveloped, and the limbs are puny and shrunken.

*b. Internal hydrorrhachis*, or dropsy of the central canal of the spinal cord, is probably, like hydrocephalus, an affection of congenital origin or of early infancy. As has already been stated, it is sometimes associated with spina bifida; it is sometimes also an accompaniment of hydrocephalus. The canal may be dilated more or less irregularly in its whole length, or may present circumscribed dilatations only, and may vary from a quarter of an inch to an inch in diameter.

As regards the etiology of chronic hydrocephalus and hydrorrhachis commencing in foetal life or early infancy, we can only say that it is said to occur especially in rickety children, and in children of scrofulous or unhealthy parentage, and that its immediate cause is probably chronic inflammation or some condition allied to inflammation, involving the lining membrane of the affected cavities.

*Symptoms and progress.*—1. The symptoms of chronic hydrocephalus are to a large extent comprised in the pathological account of the disease which has already been given, or may be surmised from the anatomical facts in relation to it there considered. As regards the invasion, it may be observed that in some cases progressive enlargement of the head, and the gradual supervention of the characteristic physiognomy of the disease, are the earliest indications of the presence of hydrocephalus; while in some instances epileptiform convulsions, repeated from time to time, or other symptoms indicative of brain-disturbance, precede the appearance of any obvious change in the form or size of the skull. We may arrange the symptoms of the disease under three heads: namely those dependent on the progressive enlargement of the skull; those connected with the general nutritive functions; and those which depend on the involvement of the nervous centres. *a.* The general shape which the head acquires, and the peculiarities presented by the stretched integuments, the eyes, the eyelids, and the face, have already been sufficiently described. We may mention, however, that fluctuation can generally be easily perceived in the course of the open sutures, and that these parts may often be seen to collapse with inspiration and to dilate with expiration. Occasionally, as in the case of Cardinal, the dilated head, like a hydrocele, is more or less transparent. The increasing size and weight of the head render it before long difficult for the child to support it, and tend, among other things, to delay the acquisition of the power of walking. The young babe is apt to rest its head constantly on the pillow, or on the nurse's lap, rolling it about from time to time; and, even when the child can walk, it still has frequently to lay its head down, or to support it with its hands, and, under any circumstances, walks with a slow and cautious gait. The latter peculiarities may be continued throughout adult life. *b.* The general nutritive functions are almost always seriously impaired. The child probably takes food well—nay, greedily; but notwithstanding this, it remains undersized and weak, and its face, trunk, and limbs become, as

a rule, emaciated and shrivelled. The bowels are often confined. *c.* Not only are epileptiform convulsions often among the earliest symptoms of hydrocephalus, but similar convulsions, or attacks of laryngismus stridulus are very apt to come on at a later period of the disease; and, even if they have been absent before, they may supervene at the time of puberty, or later. These, however, are not the only nervous phenomena present. The child is generally fretful and dull, its sight becomes impaired and sometimes lost, and occasionally also deafness ensues; the limbs are liable to spasmodic twitchings; and not unfrequently the muscles, and more especially those of the lower extremities, become rigid; they may also undergo atrophy. With the advance of age, we generally find gradually increasing hebetude or dementia—loss of memory, incapability of mental exertion, or some special incapacity for learning; we probably find, too, that the patient becomes irritable, passionate, or morose. Nevertheless he occasionally remains fairly bright and intelligent.

The duration of life is various. Hydrocephalic *fœtuses* not uncommonly die in the act of birth. Death usually occurs, however, during the first or second year, from either convulsions, coma, or intercurrent disorders. But life may be prolonged for five or ten years, or longer. In two cases quoted by Trousseau, from Frank, the ages at death were seventy-two and seventy-eight respectively. The prospect of life, no doubt, depends to a considerable extent on the bulk to which the skull and its contents have attained, and on whether the disease has become stationary or not. It not unfrequently, indeed, comes to a standstill at a comparatively early stage, and the patient survives with a large head, a protruding forehead, and other more or less obvious indications of the affection which he laboured under in infancy. But the prospects of life do not depend wholly on these conditions, for the man Cardinal, who lived to the age of thirty, had an enormously large head, and the ossification of his skull was not completed until two years before his death.

2. The symptoms due to dropsy of the ventricles, coming on after consolidation of the skull, are necessarily obscure, and none the less so that the dropsy is, almost without exception, dependent on the presence of some other grave lesion, such as tubercular meningitis, which has already produced cerebral symptoms. The special symptoms to be expected are those which would arise from pressure on the important ganglia situated on the floor of the ventricles; or, if the accumulation be acute and abundant, and in these respects resembling intra-ventricular hemorrhage, those of almost sudden and profound coma, with general paresis. There is probably always impairment of the mental functions, loss of memory, dullness and stupidity, attacks of unconsciousness or convulsions, want of control over the evacuations, and finally coma. But, besides these phenomena there may be hemiplegia, and not improbably some interference with the conductiveness of some of the cranial nerves, or some impairment of speech.

Not unfrequently, however, when, in the course of some other cerebral affection, such dropsy occurs, the patient passes into coma, in which he lies as if comfortably asleep, without either ocular or other paralysis, without

convulsions or sickness, with easy and quiet if somewhat quickened respiration, and accelerated pulse; and in which, although still able to swallow, he allows food placed in his mouth to remain there indefinitely.

3. The symptoms referrible to internal hydrorrhachis are also exceedingly vague. In some cases there is nothing either in the history or in the symptoms to indicate the presence of any affection whatever of the cord. In a case of Sir W. Gull's, and in some others that have been recorded, dilatation of the canal in the neck induced paresis of the upper extremities, with wasting of the muscles. It is natural, indeed, to assume that the symptoms of this affection should be those of pressure on the grey matter of the cord; and the symptoms which have been presented by published cases accord in the main with this assumption.

The clinical history of hydromeningocele, hydrancephalocoele, and spina bifida, and the treatment of these affections, belong rather to surgery than to medicine, and need not further occupy our attention.

*Treatment.*—The treatment of dropsy of the brain or cord is exceedingly unsatisfactory. If, indeed, the dropsy be in the adult, and secondary to some organic lesion, the probability is that it will not be diagnosed. If it were diagnosed it would not lead us to adopt any specific treatment. In the chronic hydrocephalus of children, however, we so easily recognise the presence of the disease, there is such a field for treatment offered by the slowness of the case and the gradual evolution of its various symptoms, that it is difficult to believe that everything we do must be unavailing. Yet this is certainly true of the great majority of cases. The attempt has often been made to promote the absorption of the fluid by the application of counter-irritants to the surface of the skull, or by compression of the skull by bandages, or, better, by the use of long strips of adhesive plaster applied uniformly over its surface. Trousseau states that in a case in which he adopted this treatment, sudden death was caused by the yielding of the bones of the base of the skull and the discharge of the dropsical fluid by the nose. It has been recommended to tap the distended cavities by means of a fine trocar and cannula. In using these, the puncture should be made vertically, at the edge of the anterior fontanelle, but avoiding the situation of the longitudinal sinus. A small quantity of fluid only should be removed at one time, and external pressure should be used to counteract the diminished pressure within. The operation is not dangerous, and has often been performed with temporary benefit; though no doubt there is risk that inflammation may follow, or that a vessel may be wounded. For internal use, iodide of potassium, iodide of iron, and mercurials have been employed. Sir Thomas Watson suggests, on the recommendation of an old apothecary of his acquaintance, the exhibition thrice daily of about ten grains of a pill made by mixing two parts of crude mercury with one part of fresh squills and four parts of conserve of roses. It is stated that persistence in this for several weeks has cured more than one case of the disease. It is nevertheless questionable whether any of the above plans of treatment are of real efficacy; and whether any children, who would not otherwise have got well, have recovered under their influence.

On the whole, it seems to us that it is best to aim at promoting the child's general health by attention to his diet and to his secretions, and by the use of iron, cod-liver oil, or other tonic medicines calculated to fortify his vital powers.

---

#### XIV. CHOREA (*St. Vitus's Dance*)

*Definition.*—Chorea is a peculiar convulsive disorder, for the most part of early life, characterised by disorderly movements, which in the first instance are usually unilateral but soon become general, and which tend, as a rule, to subside spontaneously after a few weeks' duration.

*Causation.*—This affection occurs mainly among children between the ages of five and fifteen, or from the commencement of the second dentition to the end of puberty. It is not, however, very uncommon to meet with it in persons between fifteen and twenty-five; and indeed it may occur, but occurs with extreme rarity, at any subsequent period of life. Dr. Graves records the case of a chemist who had chorea when he was seventy, and M. Henri Roger that of a lady who was seized with it at the age of eighty-three. Chorea attacks females far more frequently than males. This preponderance in favour of the female sex is manifested even in early childhood, but it becomes more pronounced as life advances; and of adults who are attacked very few are men. Other predisposing causes are hereditary influence, childbirth, and especially a previous attack of the disease. Trousseau draws attention to its frequent association with chlorosis; but perhaps the most interesting fact in relation to the causation of chorea is the intimate connection which it has with articular rheumatism and cardiac disease. Not only does chorea often come on in the course of acute rheumatism, not only does acute rheumatism occasionally come on in the course of chorea, but a large proportion of those victims of chorea whose cases do not fall into either of these categories have suffered from acute rheumatism at some period or other prior to the choreic attack. It has further been clearly ascertained: that by far the greater number of choreic patients present some cardiac defect; and that this, though usually of rheumatic origin, is often met with in cases in which there is no history of rheumatism, or comes on during the choreic attack without any associated implication of the joints. Rheumatism, therefore, especially rheumatism attended with pericarditis or endocarditis, must be regarded as at least one of the most efficient of the determining causes of chorea. Other causes, which operate apparently independently of heart-disease or rheumatism, are overwork, anxiety, excitement, and, above all, sudden fright.

*Symptoms and progress.*—Chorea generally comes on insidiously; and not unfrequently before any convulsive movements are recognised the child is observed to mope, to avoid its companions, to take no interest in its accustomed amusements or games, and to be incapable of fixing its attention on its work, of committing lessons to memory, or even of readily

recollecting. Indeed there is generally some real or apparent mental deficiency, associated with emotional disturbance, indicated by a tendency to caprice and fretfulness, to cry, and to be suspicious or timid. These phenomena may go along with general loss of health and impairment of the nutritive functions. The first indications of the special nature of the disease under which the patient is labouring are usually restlessness or fidgetiness, and a certain clumsiness in his movements: he cannot sit long in one place; he is constantly shifting his position or the position of one or other of his limbs; he stumbles unaccountably in moving about the room or in going up and down stairs; and he has a tendency to spill his tea or coffee, or to drop, or to knock against something else, whatever he essays to carry. The choreic movements are mostly first manifested upon one side, sometimes in the face, sometimes in the hand and arm, less commonly in the leg; but soon they involve the whole side in a greater or less degree; and after a variable time, a few days or a few weeks, the affection probably extends to the opposite side of the body, and thus becomes universal, although there often still remains preponderance of the symptoms on one side. But this mode of access, though the most frequent, is by no means invariable. In some cases when the affection comes on in the course of an attack of rheumatism, no obvious prodromal symptoms are presented. And sometimes, especially when the disease is induced by violent emotion, its onset is sudden, and the symptoms may be general from the beginning.

The phenomena of the fully developed affection, although varying largely in degree, differ but little in kind, and are for the most part exceedingly characteristic. The convulsions affect, in a greater or less degree, the whole body. They are remarkable for their disorderly character; they are not rhythmical, neither are they simple alternate flexions and extensions: but they consist in sudden impulsive movements succeeding one another at irregular intervals, and involving now one group of muscles, now another, now one part of the body, now another, now several concurrently. The convulsions generally subside in some degree when the patient is sitting or lying down; and (if they are not very violent) he is sometimes able to restrain them for a few moments; but they become aggravated whenever he endeavours to execute voluntary movements, whenever anything occurs to excite him, whenever he feels that he is being observed. It hence happens that the medical attendant rarely sees him at his best. The choreic phenomena cease during sleep and under the influence of chloroform. The affection of the muscles of the face induces constant contortions of the features; the eyebrows are at one time elevated and the forehead is thrown into transverse wrinkles; at another time the brows are knit; the eyes move suddenly and without purpose into various directions; the mouth is now opened, now closed, now drawn in various odd forms by the influence of the orbicularis and surrounding muscles. The face, moreover, wears a strangely vacant imbecile aspect. The tongue shares in these tumultuous movements. If the patient be asked to put it out, he opens his mouth wide and protrudes it with a jerk, and then as

suddenly withdraws it, the mouth and jaws closing upon it with sudden violence. If he endeavour to answer questions, the convulsive movements of the face and mouth become aggravated; and he has extreme difficulty in articulating his words, which come out in dribblets as it were, slurred over, or uttered with a peculiar drawl, hesitation, or stammer. The difficulty of speech depends partly on the convulsive action of the lips and tongue; but not unfrequently also on spasmodic affection of the larynx and respiratory muscles, which compels him to draw his breath suddenly through the laryngeal orifice with a strange sound. In some cases, even when no attempt at speech is being made, odd croaking or grunting noises are thus from time to time produced. The actions of the muscles of the head and neck are probably as incoherent as those of the face, so that the head is sometimes jerked to one side, sometimes to the other, or thrown disorderly into various odd positions. No parts usually manifest choreic phenomena more strikingly than the upper extremity; all its segments are involved in a greater or less degree; the patient hitches his shoulder; he moves his upper arm to and from his side; his forearm becomes flexed, extended, supinated, pronated; his hands and fingers execute the most grotesque and inco-ordinate movements. The general movements of the limb, when the patient uses it (when, for example, he endeavours to raise a glass of water to his lips) are curious to watch. By an effort of the will (if the case be not exceedingly severe) the glass ultimately reaches its destination, but it reaches it probably after many failures; its progress is not arrested by a series of undulatory, tremulous, or backward and forward movements of the limb, but the different segments are suddenly and violently plucked, as it were, by some invisible power first in one direction then in another, in the line of the intended movement, or in direct opposition to it, or at right angles with it. The primary movement is overlaid, as it were, during its course with innumerable uncontrollable secondary movements, which retard it, aggravate it, and distract it. The lower extremities are affected similarly to the arms. They are moderately quiet when the patient is at rest, but as soon as he begins to use them, as soon as he begins to walk, their movements become inco-ordinate, jerky, tumultuous. To quote Sir Thomas Watson's words: 'When the patient intends to stand or sit still, her feet scrape and shuffle on the floor, or one of them is suddenly everted and then twisted inwards, or perhaps is thrown across the other; and, if she endeavour to walk, her progress is indirect and uncertain; she halts and drags her leg rather than lifts it up, and advances with a rushing or jumping motion by fits and starts.' The muscles of the trunk partake in the general convulsive movements, and the body is twitched and contorted with sudden violence into all kinds of odd and unaccountable positions. Mastication and deglutition are often rendered difficult by the spasmodic movements of the muscles engaged in these operations; respiration is frequently interrupted and rendered irregular, jerky, and noisy, by involvement of the diaphragm; and sometimes, in severe cases, the sphincters of the rectum and bladder relax, and the evacuations escape involuntarily. In mild cases the patient is able to walk about, though with more or less

difficulty or clumsiness, and it may be to feed and dress himself. In more severe cases locomotion is impossible, and he has to be confined to his bed ; he becomes, moreover, quite incapable of using his hands for any purpose. In the worst form of the disease the condition of the patient is miserable in the last degree, and pitiable to behold. His features and head and neck are in constant motion ; his arms are flung out first in this direction and then in that, his fingers and hands meanwhile executing the most varied and fantastic movements ; his lower extremities are probably little less violently convulsed than his arms ; and his trunk is constantly being twisted about in bed, now into the prone position, now into the supine, is now doubled up, now straightened out again, now caught by some strange contortion.

The phenomena above described are not, however, the only nervous phenomena which attend chorea. There is always impairment of the strength of the affected muscles, some paresis—a fact especially easy of recognition in cases of unilateral chorea. In some cases, indeed, the convulsive phenomena may be replaced by hemiplegia or even paraplegia. Sometimes the hemiplegic or paraplegic symptoms precede the onset of the choreic movements. More frequently they come on in the course of the disease and supplant them. Impairment of sensation is also observable in many cases ; and its degree has more or less relation to the severity of the convulsions, or to the degree of paralysis present. Occasionally the anæsthesia is one-sided, and it may be almost absolute. The fatuous aspect of the patient in the early stage of chorea has already been referred to ; this aspect continues and even becomes aggravated during the continuance of the disease. No doubt it depends largely upon the various spasmodic movements in which the muscles of expression and those that move the eyeballs are implicated ; but there is good reason to believe it is to some extent governed by the fact that intelligence does actually fail to a greater or less extent during the presence of the malady. Emotional sensibility, on the other hand, is somewhat exalted. Sometimes the eyesight fails.

Subordinate symptoms of more or less importance are apt to attend the progress of chorea. The patient's appetite is often bad, or capricious, or lost. His bowels are confined. His nutrition becomes impaired. He suffers from palpitation, and, as has already been pointed out, he is liable to functional or organic disease of the heart, either of which may supervene in the course of his attack. There is a striking absence of febrile symptoms during the progress of the disease.

The issue of chorea is in the vast majority of cases favourable. Sometimes (if, for example, the choreic movements come on in the course of acute rheumatism and involve one arm only) the patient recovers in the course of a few days. More commonly the disease continues for a period varying between four or five weeks and three months. In some instances it is prolonged for two or three years or more. But in these cases it is usually continued by successive relapses, each coming on before the symptoms of the preceding attack have wholly disappeared. Indeed, patients who have had one attack of chorea are peculiarly liable to subsequent attacks, which

come on at irregular periods, and under the slightest provocation. Very rarely, indeed, chorea lasts for many years or for a lifetime. When the disease is fatal, it rapidly assumes aggravated proportions. The spasms are incessant; their violence and continuance prevent sleep, or allow only of occasional short snatches of sleep; they interfere seriously with the ingestion of food, and thus rapidly induce mental and bodily exhaustion. Further, the evacuations escape unconsciously, or at all events are uncontrolled, and partly on this account, partly in consequence of the constant friction to which the trunk and limbs are subjected by their never-ceasing movements, the skin becomes chafed in innumerable places, and bed-sores form over the various prominences, more especially over the elbows, hips, and sacrum. Often also the child bites its lips until they bleed; and very frequently the red portions of both lips become split by numerous deep vertical fissures. Death, which may be preceded by delirium, is generally due to asthenia. But its immediate cause may be the supervention of erysipelas or the consequences of heart disease.

The recovery from chorea (putting cardiac disease out of the question) is generally complete; the patient regains his muscular strength, and his intelligence is restored to him unimpaired. But it is not always so. Occasionally he remains feeble-minded, or even becomes insane, or lapses into a fatuous condition. In some cases, too, the implicated muscles remain enfeebled; and they may then undergo slow contraction, or atrophy, or both. In a chronic case which has been under our observation, and in which the general symptoms were undistinguishable from those of genuine chorea, the choreic movements of the lower extremities were associated with marked rigidity of the muscles, some degree of flexion at the hip and knee joints, with overlapping of the knees from the preponderant action of the adductors of the thighs, and a tendency to talipes equino-varus—facts which seem to indicate that degenerative changes of the lateral columns of the cord had supervened.

*Morbid anatomy and pathology.*—The pathology of chorea is confessedly obscure; it is not known either what parts of the central nervous organs are the seat of disease, or what is the nature of the morbid process going on in the affected parts. The facts of its unilateral commencement and general unilateral tendency point, however, to disease, either of the corpus striatum and optic thalamus, or of the corresponding cerebral hemisphere. And doubtless one or other of these parts is the main seat of the lesions on which chorea depends. But there are many features of the disease, such as the occasional implication of the muscles of phonation, respiration, and deglutition, and the frequent occurrence of functional disturbances of the heart, which would seem to imply involvement of the medulla oblongata. And the resemblance of the choreic movements to those of locomotor ataxy is certainly suggestive of implication of the cord. Then as regards the nature of the disease, its frequent connection with rheumatism and cardiac disease has suggested at least two hypotheses. One, originating with Dr. Kirkes, and since ably supported by Dr. Hughlings Jackson, is to the effect that the symptoms are due to obstruction

by minute emboli of the smaller branches of the arteries supplying the corpus striatum and contiguous parts, with consequent scattered minute patches of congestion and softening. The objections, however, to this view are obvious. Obstruction of the arterioles has been observed only in a very small number of cases, and it is doubtful if in these the obstructions were embolic or thrombotic. Besides which, it is not only difficult to believe that showers of minute emboli should be distributed throughout the minute vessels supplied to one corpus striatum or one side of the brain only, and that at some later period there should be a similar limitation of such embolic patches to the region supplied by the middle cerebral artery of the other side; but it is difficult to understand why large emboli should not be occasionally intermingled with the smaller ones, and cause sudden hemiplegia by obstructing a large vessel, and why small emboli shed simultaneously should not become blended by fibrinous coagulation around them into one or two concrete masses. The other hypothesis is that the same disease that affects the valves of the heart or the joints in rheumatism attacks also the smaller cerebral vessels or the ultimate tissue of the central nervous organs, a view which might well explain the super-vention of cardiac disease in chorea, as well as the dependence of chorea on rheumatic fever. A main objection to this view is that it is conjectural, and as yet wholly unsupported by anatomical evidence. Moreover, it fails, as also does the embolic hypothesis, to explain those cases which are due to fright or other powerful emotions, and in which, so far as we know, the heart remains sound.

It seems to us, however, that the clinical phenomena of chorea cannot possibly be referred to affection of any circumscribed region of the nervous centres; and that, whether the seat of disease be thus limited or not, the embolic hypothesis is altogether inadequate as an explanation of the nature of the morbid processes to which the clinical phenomena are linked. The symptoms are partly intellectual, partly emotional, and referrible partly to the functions of the voluntary muscles, partly to the cutaneous sensibility, and partly also to the bulbar nerves, which subserve articulation, deglutition, respiration, and the motor functions of the heart; they would seem, therefore, to be connected at the same time or successively, and in different degrees, with the cerebral convolutions, the ganglia at the base, the pons and medulla, and the spinal cord. The valuable paper read by Dr. Dickinson before the Medico-Chirurgical Society is strongly confirmatory of this view. He shows, from the results of careful post-mortem examinations made on several fatal cases of chorea, that there is a general tendency to dilatation of the smaller vessels, more especially the arteries throughout the substance of the brain and cord; that this dilatation is attended with exudation into the tissues immediately surrounding the vessels, and occasionally with small hemorrhages indicated by the presence of blood-crystals and the like, or patches of sclerosis; that these changes are most advanced in the corpora striata, in the nervous matter in the neighbourhood of the trunks of the middle cerebral arteries, and in the posterior and lateral portions of the grey matter of the cord, mainly

at the upper part; and, further, that in all these regions the morbid conditions tend to be symmetrically arranged. And on the basis of these facts, and admitting that chorea is associated generally with rheumatism, in the larger proportion of cases with heart-disease, and in some cases with no inflammatory or structural disease of any organ, he comes to the conclusion (in which we are disposed to concur) that chorea depends 'on a widely spread hyperæmia of the nervous centres, not due to any mechanical mischance, but produced by causes mainly of two kinds—one being the rheumatic condition, the other comprising various forms of irritation, mental and reflex, belonging especially to the nervous system.' The tendency which the vascular changes have (on Dr. Dickinson's showing) to induce sclerosis in the tissues which surround the vessels well explains the wasting of muscles, rigidity of limbs, and permanent paralysis, which occasionally complicate chorea or supervene upon it.

*Treatment.*—For few diseases have so many specific remedies been vaunted as for chorea; yet few diseases are really so little amenable to treatment. It must never be forgotten, in weighing the value of medicines in this affection, that the great majority of cases tend to get well spontaneously in the course of a few weeks. Sydenham recommended bleeding and tartrate of antimony, and 'cured' his patients by these means; and even Sir Thomas Watson advocates local bleeding, when there is a fixed pain in the head. Large doses of antimony, indeed, have been strongly recommended by many physicians. Iron is a favourite remedy; so is sulphate of zinc, given in doses, to commence with, of a grain or two three times a day, which are slowly increased by successive increments, until from 20 to 40 grains are given at a time; so also is arsenic given usually in small doses (four or five minims of the liquor arsenicalis thrice daily), but sometimes in doses gradually increased to half a fluid drachm or more of the same preparation. Iodide of potassium is lauded by some; bromide of potassium by others; phosphorus by others. Of medicines derived from vegetable sources we may name turpentine, strychnia, cannabis Indica, opium, belladonna, and various anti-spasmodics. Exercise, frictions, and cold baths, more especially shower-baths, have all their advocates. We must confess that in our own opinion few, if any, of the above remedies have any real influence over the course of the disease; if, however, we have any bias, it is in favour of arsenic, given in small doses, and continued for some length of time. We believe, however, that real benefit accrues in a considerable number of cases from improvement of the general health; that in this point of view tonics (among which iron holds an important place) are useful, as also are careful attention to hygienic measures, good, wholesome diet, early hours, avoidance of excitement, gentle exercise, cold or tepid bathing, and change of scene and air. Again, our treatment may often be usefully directed by the nature of the malady (if any) with which the chorea is associated; thus when rheumatism is present, or chorea is a legacy left by rheumatism, anti-rheumatic treatment may be of great service. In those severe cases in which the convulsive movements are

incessant, and the patient has little or no rest, and death consequently threatens, narcotics and stimulants would seem to be indicated. The inhalation of chloroform arrests the convulsive movements so long as the patient is under its influence ; opium, morphia, or chloral in large doses has the same effect. But it must be admitted that, notwithstanding the temporary ease they give, the progress of the disease towards its fatal end is rarely, if ever, retarded by their use. The patient should then be supported by food and stimulants. Further, every precaution should be taken to prevent the patient from injuring himself in his contortions, and all sores that form upon the surface of the skin should be at once treated, and protected from further injury.

It may be pointed out, in conclusion, that chorea is apt to spread among children, apparently by imitation ; that choreic patients are often rendered worse by their association with patients of the same class ; and that hence precautionary measures directed against such accidents should be taken.

## XV. EPILEPSY. ECLAMPSIA. INFANTILE CONVULSIONS

### A. *Epilepsy (Morbus comitialis vel sacer)*

*Definition.*—It is difficult, if not impossible, so to define epilepsy as within the limits of a mere definition to include all the varieties of form which it assumes. Speaking generally, it is a functional disorder of the nervous centres, characterised by sudden seizures of temporary duration, and occurring at irregular intervals, in which the patient either loses consciousness or presents some other form of mental disturbance, or has tonic or clonic convulsions, or all of these phenomena in sequence. For a true conception of the disease, it must be understood that, however mild the attacks may be, all the phenomena which have been enumerated are potentially present in them, and may be expected to occur in combination during the progress of the disease.

*Causation.*—The causes of epilepsy are very obscure. The disease has been attributed to all sorts of circumstances which have probably little or no influence in its production. Among those to which most importance has been attached may be mentioned sudden fright, the witnessing of an attack of epilepsy, long-continued anxiety, over-work, drink, abuse of absinthe, and venereal excesses, especially masturbation. But their importance as exciting causes has been greatly over-estimated. It is considered by Trousseau that the real share of each one of them (excepting fright) in the production of the disease is yet to be proved ; and Russell Reynolds remarks of excessive venery and masturbation that far too much importance has been attached to them. Hereditary predisposition, on the other hand, exerts a remarkable influence over the development of epilepsy. It is to be observed, however, that it is not so much epilepsy itself which is hereditary (although, no doubt, it is so in a high degree) as that epilepsy becomes hereditary in families among the members of which neuroses, such as epilepsy, insanity, hysteria, and the like,

prevail. It is not uncommon to find in such families that several of the children are epileptic, or that one is epileptic, one suffers from chorea, one is an idiot, and so on. But the predisposition to epilepsy may be acquired; for it is certain that many of those persons who subsequently become epileptic have suffered in infancy from convulsions, which were induced by teething or other accidental circumstances. Epilepsy occurs pretty equally in both sexes. The first attack may come on at any period of life—in early childhood or extreme old age—but it occurs far more frequently between the ages of ten and twenty (more precisely, perhaps, during the time of puberty) than it does at any other period of life. Dr. Reynolds points out that there is comparative immunity between the ages of twenty-five and thirty-five; but that the outbreak of the disease becomes comparatively frequent again about the age of forty. After this time its primary appearance is extremely rare.

*Symptoms and progress.*—The phenomena of epileptic attacks are so various, they differ so widely from one another in different cases, both in their characters and in their grouping, that it is impossible to give a comprehensive, and at the same time graphic, account of them, excepting by the aid of illustrative cases. Our space forbids the adoption of this course. We shall therefore begin with the description of a typical attack of the disease, and then discuss the variations to which attacks are liable.

The epileptic fit is not unfrequently preceded by a well-marked prodromal period, lasting in different cases from a day or two to a few seconds. But, under any circumstances, the fit itself comes on suddenly; the patient probably utters a cry, loses consciousness, and, if standing, falls down on his face or on the back of his head as if shot; his muscles become rigid, especially, perhaps, those of one side, and at the same time slowly contract; and respiration ceases. After these phenomena, which constitute the first stage of the attack, have lasted for a few seconds, the second stage supervenes. This is characterised mainly by return of respiration, lividity of surface, distension of the veins of the head and neck, clonic spasms, which are mostly unilateral, biting of the tongue, and continuance of unconsciousness. At the end of a minute or two this stage also comes to a conclusion, the lividity disappears and the convulsions cease, but the patient probably still continues insensible; presently, however, consciousness returns in some degree, and he either rapidly recovers, or remains confused or maniacal, or in a state of stupor for some hours, or it may be a day or two, before complete recovery takes place.

The prodromal period is present probably in about half the total number of cases, and if present in one attack is most likely present in other attacks occurring in the same patient. Moreover, under such circumstances the premonitory symptoms continue probably, at any rate for a time, of the same kind. Those which precede the attack by some hours or a day or two are the least common, and, although perhaps apparent enough to the patient or his friends, are on the whole slight in degree and vague. They consist, for the most part, in some modification of the

patient's intelligence, feelings, or habits; he gets dull and incapable of mental exertion or of attention to business, sullen or low-spirited; or his manner and conversation become sparkling and lively, and his spirits unaccountably buoyant and jovial—he may even be furiously maniacal, or there is simply something in his look (a wildness in his eye or a dullness and heaviness of expression) which is not natural to him. The more characteristic premonitory symptoms are those which precede the fit by a few minutes or a few seconds only. They are remarkably various. In some cases they consist in the spasmodic contraction of certain muscles: the expressional muscles of one side of the face twitch; or the hand and arm are convulsed, and gradually carried upwards towards the face; or the lower extremity is equivalently affected; or the muscles of one side of the head and neck contract and carry the face over the opposite shoulder; or the muscles of several or of all these regions are simultaneously involved. Sometimes the epileptic fit is preceded by vertigo, or sickness, or by severe pain or some undefinable sensation referred to the head, throat, chest, abdomen, or some other part. Not unfrequently the premonition is furnished by what has been termed the epileptic aura (a sense of coldness, heat, or pain, starting from some point, say the finger or toe, the abdomen or chest, or it may be from the seat of some former injury), which seems gradually to ascend until it reaches, as the case may be, the epigastrium, the præcordial region, or the head, when insensibility suddenly supervenes. In some cases the attack is ushered in by some hallucination of the senses: the patient perceives some peculiar smell; or he hears strange sounds, and, it may be, voices; or he sees definite forms before his eyes—animals, departed friends, witches, devils. Not unfrequently, again, the premonitory symptoms consist in some odd mental disturbance: the patient experiences a sudden horror or trouble, or he finds himself engaged in some special train of thought or perplexed by some problem or the plot of some story or strange combination of circumstances. It is curious that these mental perplexities which seize upon the patient are often entirely forgotten after the occurrence of the fit, yet that the same perplexity is repeated (exactly as the drawing up of the arm or the occurrence of an aura is repeated in other cases) before every epileptic attack.

The most constant feature of the first stage of the fit is the sudden onset of absolute unconsciousness. This may be momentary only, or may be prolonged throughout the whole of the first and second stages, and for two or three minutes or more. As we shall afterwards show, it is sometimes absent. This unconsciousness while it lasts is profound; the patient neither sees, nor hears, nor feels, nor can be roused by any means at our command. The convulsions which attend this stage are tonic; they consist in the supervention in the affected muscles of great rigidity, attended in the first instance with fibrillar movements, and a tendency for certain muscles gradually to overcome their antagonists. They are rarely general, or if general they affect one side more powerfully than the other; they are, in fact, almost always unilateral, and sometimes

limited to the side of the face or head and neck, or to the arm. The face becomes hideously distorted, and the tongue probably thrust between the teeth; the head, from contraction of the sterno-mastoid and other muscles, drawn down obliquely on one side, the face being thrust over the opposite shoulder; the trunk contorted; and the arm or leg flexed or extended. At the same time the respiratory and laryngeal muscles become fixed, and the acts of respiration cease entirely. These spasms are sometimes wholly absent. The epileptic cry which ushers in the attack occurs only in a limited number of cases. It varies in character, is sometimes a loud shriek, sometimes a hoarse groan, and is usually very distressing to hear. It usually occurs (as Dr. Reynolds points out) once only, but it may be prolonged throughout the whole period of insensibility. The pupils are dilated and insensible to light. If the patient be closely observed at the onset of his attack, his face will usually be seen to be suddenly overspread with a death-like pallor, which persists for a few seconds, but gradually, during the progress of the first stage, becomes replaced by redness and turgidity. In some instances no change whatever of colour can be discovered. In association with the phenomena here enumerated there is usually extreme feebleness of pulse. Although the patient generally falls with sudden violence, he sometimes slips down quietly, almost as if by design; and if the loss of consciousness be momentary only, he sometimes remains motionless, standing or sitting, or merely staggers. The first stage usually lasts from ten to thirty or forty seconds.

The second stage is attended with continuance of unconsciousness. The face has usually by the time of its commencement become livid and bloated, and the veins of the head and neck distended; but this lividity and over-distension of the vessels slowly subside during its continuance. The tonic spasms cease, to be replaced by clonic spasms. These, which consist in alternate powerful contractions of flexors and extensors or other groups of antagonistic muscles, may be general; but they are more commonly one-sided and limited to those parts which had previously been the seat of tonic contraction. The pupils oscillate, the eyelids and muscles of expression work, the mouth is alternately open and closed with violence, and the protruded tongue, caught between the teeth, is apt to get severely bitten, the muscles of the head and neck, and those of the trunk, are convulsed, and the arm and leg execute powerful movements of extension and flexion. At the same time probably the fæces and urine are discharged involuntarily. The respiratory acts are resumed at the commencement of this stage, and during its course are violent, jerky, noisy, and laboured. The skin is cold; profuse sweats break out; the pulse is full; the heart beats violently. Mucus accumulates in the mouth and fauces, and, mingled with the blood yielded by the bitten tongue, escapes from the lips. The symptoms of this stage, violent in the beginning, gradually subside; and at the end of a few seconds, a minute, or at most two or three minutes, the patient draws a deep sigh, and the second stage is completed.

The condition of the patient in the third stage varies. Sometimes he

recovers almost instantaneously, and appears at once in his normal health ; but more commonly he lies for some minutes or for half an hour in a condition of profound coma, from which it is impossible to rouse him. Sooner or later, however, consciousness slowly returns ; he opens his eyes and gazes stupidly or wildly about him ; he tries to speak, but mumbles unintelligibly or incoherently, or fails to produce any articulate sound ; he tries perhaps to get up, and his movements and demeanour resemble those of a drunken man ; sometimes he becomes wildly maniacal, sometimes falls into a state of trance or ecstasy. We have met with one case in which the patient always recovered laughing. It not unfrequently happens that the patient lapses into a profound sleep, interrupted it may be from time to time by slight convulsive twitchings. Muscular weariness, a sense of general bruising, headache, vertigo, restlessness, severe mental or emotional disturbance are apt to remain for some hours or even for a few days after the fit. After the attack the patient often passes a large quantity of limpid urine ; and, owing to the extreme distension of the vessels of the head and neck and upper part of the trunk, minute extravasations of blood are apt to occur during the fit, and the surface of these parts to become thickly studded with persistent hemorrhagic points, or petechiæ.

The above account applies to those fits, typical in their severity and in the sequence of their phenomena, to which the names *epilepsia gravior* and *haut mal* have been given. But in a large number of cases either the fit does not pass beyond the prodromal stage ; or various of the stages are absent, or so rapidly completed, or so blended with one another, that they escape observation ; or some of the features of the malady are aggravated ; or new features are superadded. Most of these attacks come under the denomination of *epilepsia mitior*, *petit mal*, or *epileptic vertigo*.

In some cases the patient is affected with an occasional sudden spasm of one side of the face, or of one sterno-mastoid ; or his hand closes, and the arm is gradually drawn up or flexed ; or he experiences some one of those sensory hallucinations which have been previously enumerated ; or he has an aura, or a sudden attack of headache, giddiness, sickness, or faintness. In other words, he is attacked with some one of the prodromal symptoms which are known to usher in epilepsy. Now it does not at all necessarily follow that the sudden occurrence of such phenomena, or even their occasional repetition, proves that the patient is epileptic ; but it is certain that, of those persons who suffer from them, some become epileptic sooner or later ; and that those epileptics whose fits are preceded by warning symptoms not unfrequently have such warnings without fits following them. There can be no doubt that such attacks must, under these circumstances, be regarded as epileptic. They are, in fact, abortive epileptic fits. In some instances the patient's seizures consist in little more than a momentary interruption to the continuity of his thoughts. He is engaged in talking, and suddenly for a second or two becomes quiet, and then resumes the thread of his conversation as if nothing had occurred ; or instead of ceasing to speak he may utter some incoherent sounds, or words and expressions utterly alien to the subject in which he

was engaged. If he be closely observed at this moment, his pupils will probably be seen to dilate, his face to become momentarily pale, and then perhaps with returning consciousness a little more congested than natural. During the momentary attack the patient may become absolutely unconscious, and his mind may be a blank ; or, although unconscious to everything about him, he may be the subject of a sudden trouble, perplexity of mind, or horror—some momentary nightmare, as it were. Sometimes he utters a shriek and reels or staggers, or performs a rotatory movement, and then without falling to the ground recovers. Sometimes he is seized with unconsciousness lasting for a few seconds, or for a minute or more, and remains sitting or standing, or in whatever other position the fit surprised him in, his features meanwhile being perfectly passive or presenting convulsive twitchings. In most cases the wholly unconscious patient will go on during his unconsciousness with the work in which he was engaged at the time of seizure : if walking he will continue to walk, if running he will go on running. Trousseau mentions the case of a young amateur violinist who, during attacks of short duration, would go on playing with perfect accuracy as if he were still in his ordinary senses. There are other cases, again, in which the patient, during his attack of unconsciousness, performs strange actions, which have nevertheless an aspect of purposiveness about them, but of which he has no recollection whatever when consciousness returns. They seem, in fact, like the translation into action of the fragment of a dream. Thus, sometimes, while walking, perhaps in the street, he all at once begins to run rapidly, avoiding all obstacles, and then coming to discovers himself unaccountably far from his destination or from the place at which he lost his senses. Trousseau cites the case of a magistrate who, in such an attack, suddenly left the court over which he was presiding, went into the council-chamber, made water in a corner of the room, and returned to the court entirely ignorant of the strange act he had committed. Sometimes the patient will dance or sing, or peer about in various directions as if in search of something which he has lost or mislaid. But perhaps the most important, if not the most remarkable, of these aberrant forms of epilepsy are those in which the patient is seized with sudden and unaccountable fury, tears his clothes, or destroys anything that is near him, belabours the friend or the servant that is with him, or rushes out of the house and attacks the first stranger that he meets, or jumps from the window, or in some other way maims or kills himself, and moreover not unfrequently accomplishes such acts with apparent definiteness of purpose. Thus a husband, apparently waking out of sleep, will beat or strangle his wife with the utmost ferocity ; a man walking along the street will, at the moment when the impulse is upon him, make an unprovoked and violent onslaught on whoever chances to come near. Now it must be borne in mind that in all the varieties of seizure, in all the different forms of epileptic vertigo, which we have been considering the only appreciable part of the attack may be the temporary unconsciousness or delirium, together with the various specific motor phenomena which have been enumerated, and utter uncon-

sciousness or forgetfulness of what has passed in the attack. There may be no premonitory symptoms, no tonic or clonic convulsions, no change of colour, no succeeding bodily or mental suffering. On the other hand, careful observation will often reveal the presence in a modified form of some of the more ordinary features of the typical epileptic fit. There may be slight premonitory symptoms; there is generally a sudden pallor or ghastliness at the commencement of the attack, soon followed by redness or lividity, and in connection therewith dilatation of pupils, rolling of the eyes, or twitching or more violent convulsive movements of the muscles of the face or one of the limbs; and, further, vertigo, confusion of mind, or other such conditions may remain for a longer or shorter time after the subsidence of the fit.

The first epileptic fit may also be the last; but in the great majority of cases it forms the prelude to subsequent attacks, which may come on at various intervals for months or years or during the whole subsequent lifetime of the patient. Sometimes the fits recur with more or less irregularity at intervals of a week, a month, two or three months, or a year, or more. There may then be a single fit at each recurring period, or there may be two or three, or a dozen, or more, succeeding one another during a period of twelve or twenty-four hours. In some instances frequent fits occur habitually day and night. It occasionally happens that, as the general health improves or age advances, the fits become less and less frequent, and at length recur at irregular intervals of years, or disappear altogether. It must be borne in mind, however, that those who have once been epileptic, even if five, ten, or a dozen years have passed since the last attack, are still not unlikely to have a relapse; and, again, that patients whose fits have hitherto occurred only at long intervals not unfrequently suffer from aggravation of the disease—the fits rapidly increasing in frequency, and recurring in large numbers day and night for weeks together. Sometimes, when the attacks follow one another very rapidly, the patient falls into the status epilepticus; a condition in which he remains insensible for many hours, sometimes for a day or two, and which has often been referred to the persistence of a single fit: it is made up, however, of a succession of fits, linked together by persistent epileptic coma.

Convulsive fits recur, as a rule, much less frequently than attacks of epileptic vertigo; yet when they recur at long intervals they are very liable to be repeated several times within a limited period. Epileptic vertigo may come on habitually twenty, thirty, or forty times, or even as many as a hundred times in the day. According to Dr. Reynolds, cases of the *haut mal* are nearly twice as common as cases of the *petit mal*; there can be little doubt, however, that the *petit mal* is much more frequent than is generally supposed, and that many persons accounted healthy, and who never consult a doctor, are liable to occasional slight seizures. Attacks of the *haut mal* not unfrequently, however, alternate with those of epileptic vertigo; and still oftener patients who are subject to the former have abortive seizures represented by the aura only. On

the other hand, although epileptic vertigo often constitutes the only form of seizure from which patients suffer, attacks of a severer kind are in such cases always liable to supervene.

The circumstances which determine the epileptic fit in those who are liable to fits are not generally discoverable. They often, at all events when they first appear, come on only in the night, either, it is said, at the moment of going to sleep or at the moment of waking; and, even when they take place both day and night, they often occur mainly at night-time. It is not uncommon for them to attack women at the monthly periods; yet it still more frequently happens that epileptic women do not suffer specially at the time of menstruation; and they escape, as a rule, during parturition, a time at which eclampsia has a special tendency to supervene. In some cases the fit seems to be induced by severe mental labour, by emotion, by a debauch. It has occurred during the act of coitus. Sometimes, when the attack is preceded by an aura starting from some accessible point, it may be induced by irritation of that point. Thus we knew one case in which it was invariably excited by compression of a certain tender spot on the abdominal wall; and we have met with another in which for many weeks fits were brought on day and night whenever the patient's legs were moved voluntarily or involuntarily, whether he was awake or asleep.

The condition of epileptic patients in the intervals between their seizures is very various. In a large proportion of cases they appear to be in the enjoyment of perfect mental and bodily health. Not unfrequently, however, some peculiarities reveal themselves sooner or later in connection with their nervous organism. They become low-spirited or taciturn, or querulous, fidgety, or excitable; or there may be a little failure of memory, or some slowness of apprehension, or difficulty of application. The most remarkable mental phenomena, however, are those which are included in the term 'epileptic mania.' The attacks of mania resemble those which have already been referred to as constituting a part of the epileptic paroxysm; but they may occur independently of the epileptic fit, and may last from a few hours, or two or three days, to a week or two, or more. They are remarkable, as a rule, for the suddenness of their invasion and the suddenness of their subsidence. They present two varieties, which by Dr. Falret are termed respectively *petit mal* and *haut mal*. The latter is furious, attended with sudden attacks of uncontrollable violence and ideas and hallucinations of a terrifying character; the language of the patient is less incoherent than that of many other lunatics, and it is remarkable that each successive maniacal attack repeats the main features, in almost every detail, of the attacks that have gone before. In the *petit mal* the patient is morose and despondent, and mistrusts and fears those who are about him; he is impelled, as it were, by some superior power, in obedience to which he performs acts that he would not otherwise do; he leaves his home and occupation, wanders about, and is liable to sudden outbreaks of passion, in which he will attack, destroy, or kill whatever comes in his way or commit suicide. In both forms of mania the comparative

coherence of the patient might lead one to suspect that he was either malingering or under the dominance of simple revenge or passion. Yet his memory of what has occurred in his attacks is exceedingly defective : sometimes he recollects nothing ; more often he recollects fragments of what has happened, as of a dream ; but he can rarely call to mind all that has taken place, and perhaps forgets the main incidents entirely.

In some cases of epilepsy the patient's mind undergoes gradual deterioration, and he becomes imbecile or idiotic. It is said to be principally in the case of the *petit mal* that this result ensues.

Epilepsy does not tend immediately to shorten the duration of life ; nevertheless it materially increases the risks to life. The epileptic patient is liable to incur serious accidents : to fall into the fire ; to tumble into the water ; to be drowned while bathing ; or to fall from his horse, or from a scaffolding, or over a precipice ; he may also be choked when eating, or asphyxiated as he lies in bed. Very rarely the fit itself proves fatal without extraneous aid ; when it does the patient dies from asphyxia during its first stage, or from exhaustion or coma during the status epilepticus.

From the multiform characters which epilepsy presents, its diagnosis is often a matter of extreme difficulty. When occurring only at night-time, it not unfrequently happens that the patient is ignorant of the nature of his malady, or even that he has anything the matter with him. Yet, even in cases of this kind, a hint, or an admission, or the statement of some special occurrence may awaken the suspicions of the medical man. Thus the patient on waking up feels weary, sore, and bruised ; or he is uneasy, with giddiness, headache, or confusion of mind, from which he slowly recovers ; or he finds that his tongue is sore, and that there is blood upon his pillow ; or he notices petechial spots or ecchymoses upon his face, neck, and chest, or in the conjunctivæ ; or he finds that he has passed his evacuations into the bed, or that he has dislocated his shoulder or otherwise injured himself. Now any of these accidents may occur independently of epilepsy ; but if they recur from time to time, and especially if two or three be associated, the evidence in favour of epilepsy becomes very strong.

The actual epileptic attack may be confounded with apoplexy or with hysteria. The true apoplectic attack, in which the patient falls down suddenly comatose, is now generally allowed to be epileptic or epileptiform. The point, therefore, to determine in such cases is not whether it be apoplectic or epileptic, but what is the pathological condition on which the loss of consciousness depends. The distinctions between hysterical and epileptic fits are generally well marked, and little doubt usually remains when the history of the case is obtained. Still the affections appear to run into one another, and the condition termed hystero-epilepsy forms the link between them. The main points to bear in mind in forming a diagnosis are (apart from the patient's history) the usually much greater violence and much longer continuance of the paroxysm of hysteria, the more general distribution of the convulsive movements, and the generally great and persistent noisiness of the patient. The

hysterical patient, moreover, is seldom unconscious, can generally be roused without much difficulty, rarely bites her tongue, passes her evacuations into the bed, or injures herself; the skin, too, is hot, and the pupils act under the influence of light.

Few diseases are so frequently feigned as epilepsy. The coarser features of the *haut mal* are so striking that few persons can fail, with a little study, to imitate them fairly well. There are various points, however, about the real attack which the actor does not observe or cannot copy. Thus he neither bites his tongue nor passes his evacuations into his trousers; his pupils are probably not dilated, and certainly not insensible to light; and his skin becomes hot and perspiring with his violent muscular exertions. Further, when he falls he takes care not to hurt himself; he over-acts the convulsive part of the attack, but probably fails in details; moreover, he is alive to what is going on around him, takes furtive glances at the bystanders, and gives distinct evidence that he feels if he be hurt, or if a jugful of cold water be thrown over him. Still there may be real difficulty; and it behoves the physician not to commit the error of assuming that a real epileptic is malingering. The stage which succeeds the period of insensibility is one not likely to be copied by a cheat; yet it is a stage in which it is often not difficult to persuade oneself that a patient is shamming.

*Morbid anatomy and pathology.*—There are few diseases about the pathology of which we are so entirely ignorant as we are about that of epilepsy. It has been referred to anæmia of the nervous centres; it has been referred to hyperæmia; it has been assumed that the cerebral convolutions, the ganglia at the base, or the pons and medulla oblongata are mainly at fault; and the disease has been regarded as one involving the nervous centres as a whole. Morbid anatomy scarcely helps us; for in the rare cases in which death has occurred in a fit, little or nothing more than hyperæmia has been detected, with in some cases hemorrhage into the perivascular sheaths of the smaller vessels; and when chronic epileptics have been examined post mortem, either the brain has looked healthy, or it has appeared to have shrunk somewhat, or there has been some induration of the white matter, or some thickening of the walls of the minute vessels with traces of previous hemorrhage in their vicinity. These lesions, however, have been mainly recognised in the brains of those whose epilepsy was associated with chronic insanity or dementia. Experiment has clearly shown that anæmia of the brain, suddenly produced, causes epileptiform convulsions; but, on the other hand, extreme congestion of the brain, as occurs during the prolonged paroxysmal cough of pertussis, is also followed by insensibility associated with convulsive twitchings. There is every reason on clinical grounds to believe that in the epileptic paroxysm the brain is successively anæmic and congested. The extreme pallor which overspreads the surface at the commencement of the attack, and which has been observed, we believe, by Dr. Jackson to pervade the retinal vessels as well, may be taken as a clear indication that the brain itself is anæmic at that time. And the great venous and

capillary congestion which almost immediately afterwards replaces that pallor, coupled with the presence of post-mortem congestion and capillary hemorrhages in the brain in fatal cases of epilepsy, shows clearly that the early anæmic condition of the brain is soon succeeded by notable congestion. But, even if it be allowed that anæmia of the brain is the cause of the earliest epileptic phenomena, including the tonic spasms, it is obvious that it is not the cause of the clonic spasms which come on with congestion. Dr. Marshall Hall, who clearly recognised this sequence, referred the clonic spasms to the congestion which followed upon the cessation of the respiratory acts, and recommended the performance of tracheotomy with the object of preventing their supervention, and so of robbing the disease of its chief horrors. But if the epileptic phenomena depend on mere congestion or anæmia, this must obviously originate in some functional disturbance at the source of the vasomotor nerves which are distributed to the cerebral vessels.

The medulla oblongata and upper part of the cord are regarded by Dr. Reynolds as the primary seat of epilepsy. And MM. Luys and Voisin, as the result of careful post-mortem investigations, conclude that the parts which mainly suffer in this affection are the medulla oblongata, corpora striata, cerebellum, and other parts at the base of the brain. On the other hand, it has been shown by Brown-Séquard that epileptic convulsions may be artificially induced in guinea-pigs as a consequence of section of one of the lateral columns of the cord anywhere between the medulla and tenth dorsal vertebra. It must be admitted, indeed, that both tonic and clonic convulsions may be of spinal origin, and that in epileptic convulsions the motor tract of the cord must necessarily be largely concerned; at the same time, from the special implication of the nerves at the base of the brain, there can be no doubt that the motor nuclei in the medulla oblongata and on the floor of the fourth ventricle and iter must be at least equally affected; further, from the general unilateral tendency of the spasms or predominant action of the muscles of one side when both sides are involved, there is great reason to suspect that, however much the various nuclei of the motor tract are involved, they are dominated by the corpus striatum. Still, when we look to the clinical facts of epilepsy, and recollect that convulsion is by no means the most frequent or the most important element of the attack, and that when it occurs it is usually preceded by some aura, sensation, spasm, or hallucination, and is attended from the beginning either with absolute loss of consciousness or with a dreamy condition in which there is often a total insensibility to external impressions, it is impossible not to acknowledge that, however seriously the cord, medulla, and ganglia at the base of the brain may be implicated subsequently, the earliest phenomenon must be connected with some limited spot in the nervous centres, which, though different for different cases, is probably always the same for the same case; that the pain, sensation, giddiness, or hallucination is probably of central origin; and that from this primarily affected spot a sudden influence is discharged over the sensorium and the sensori-motor regions of the cerebrum, which as regards

the sensorium either annuls consciousness wholly or in part, or perverts it, and, as regards the motorial system, either excites it to unwonted or perverted action, or arrests its operations. There is reason, therefore, to believe that the epileptic fit commences before the brain becomes anæmic, and room, therefore, to question whether this anæmic state of the brain is the cause or the consequence of the symptoms which accompany it. There is equal reason, we think, to doubt whether the congestion which follows the anæmia is the cause of the clonic contractions and of the various phenomena which attend their occurrence; and whether, finally, the after-symptoms are to be referred (as some suppose) to carbonic acid poisoning. The pathology of the affection is, we repeat, obscure, and we do not attempt to elucidate it.

*Treatment.*—During the epileptic attack there is usually little to be done beyond preventing the patient from injuring himself, and removing all sources of pressure from his neck. It is often well to prevent him from biting his tongue by inserting a pad between his teeth. Convulsions may often be allayed by the inhalation of chloroform; and it may be advisable, when the congestion of the face is extreme and long-continued, to remove blood from the distended vessels of the neck. Not unfrequently, when the attack is preceded by a warning of sufficient duration, it may by proper management be averted. Among measures which have been successfully adopted for this purpose are: the inhalation of chloroform or ammonia, the administration of a dose of sal-volatile or ether, the application of a ligature above the point from which the aura springs, or the forcible prevention of the closing of the fingers or the flexion of the arm, when such movements constitute the premonitory symptoms. Latterly Dr. Crichton Brown has, for the same purpose, had recourse, with success, to the inhalation of nitrite of amyl.

The measures which have been employed to cure epilepsy are innumerable. Many drugs have been administered with more or less success, among which may be enumerated the sulphate and oxide of zinc, arsenic, copper, iron, nitrate and oxide of silver, and the bromides of potassium and ammonium; belladonna, digitalis, strychnia, opium, and Indian hemp; as also musk, valerian, and assafœtida. The list might easily be extended. Of the above, those which have perhaps enjoyed the widest reputation are the salts of zinc, silver, and arsenic, belladonna, and the bromides of potassium and ammonium. Belladonna has been strongly advocated by Trousseau, who recommends that it be given in the form of a pill containing  $\frac{1}{3}$  grain each of the extract and powdered leaves; or that in its place the  $\frac{1}{100}$  of a grain of the sulphate of atropia be administered. He recommends that during the first month one of the pills be given daily, and that a pill per month be added, until the daily allowance of pills amounts to from five to twenty. He strongly urges that the pills be given either night or morning, according as the fits are nocturnal or by day, and invariably at the same hour in the same case. Bromide of potassium has been the favourite remedy of late years, and there is no doubt that its use is often highly beneficial and sometimes curative. The dose should vary

from 10 to 30 grains three times a day, and it should be given for a considerable length of time. But probably more important than medicine is careful attention to hygiene; the patient's habits should be ascertained, and, if in fault, corrected; masturbation and excessive venereal indulgence should be checked; over-eating, and especially over-drinking, late and irregular hours, and excitement of all sorts should be avoided. He should live quietly, keep good hours, take nourishing, wholesome food, eschew alcohol as far as possible, attend to the condition of his evacuations, and, if need be, have change of air and scene. It is often a question whether the patient should give up work: whether, if a man, he should cease to engage in his ordinary business pursuits; if a child, give up learning. The answer to such questions must depend on the special circumstances of the case. No doubt, when the fits are severe and frequent, it may be well to cease, at least for a while, from all mental labour and sense of responsibility; but in the great majority of cases there is every reason to believe that a certain amount of mental occupation, and it may be added of bodily exercise, is beneficial to the patient, and that, on the other hand, entire cessation from work is injurious. As a rule, therefore, the child should pursue his studies, the adult his usual avocations; but neither should be allowed to push his work to excess. Lastly, counter-irritation, setons and issues behind the neck, shower-baths, cold baths, and ice along the spine, and even the removal of the clitoris or of the testicles have each had their special advocates. There are no sufficient grounds, however, for believing any one of these measures to be really beneficial.

### B. *Eclampsia.*

*Definition and causation.*—This is the name now commonly applied to all those varieties of epileptiform convulsions which occur accidentally, so to speak, in dependence on some specific lesion or the presence of some special pathological or physiological process. Eclampsia may be one of the phenomena consequent on fracture of the skull, effusion of blood into the brain, or obstruction of a cerebral artery; it may be developed in connection with the growth of an intracranial tumour, whether this be tubercular, syphilitic, carcinomatous, hydatid, aneurysmal, or other; it is liable to occur when there has been sudden and copious loss of blood, when the brain is deeply congested, or when certain poisons circulate with the blood; it thus attends poisoning by hydrocyanic acid or absinthe, the retention of effete matters in the blood from renal disease, and in young children is often one of the earliest indications of the operation of the scarlatinal poison or that of other infectious disorders. Further, it is often induced by reflex action, and thus sometimes occurs during parturition, and in children is a frequent consequence of teething, gastro-intestinal disturbance, and many slight local conditions which in older persons would cause little or no inconvenience.

*Symptoms and progress.*—The fits of eclampsia are for the most part undistinguishable from those of true epilepsy. They may be exceedingly slight, they may be robbed, as it were, of one or more of the recognised

stages, or they may present in a typical form all the sequence of events characteristic of the *haut mal*. But they are often less sudden in their invasion; the patients are less liable to lose consciousness absolutely than true epileptics are; the fits much more frequently have a fatal issue, either from coma or from exhaustion; and they are much more irregular in their occurrence—probably, however, becoming more and more frequent and severe if the affection on which they depend is a progressive one, or ceasing permanently if their cause is removed. Further, with the exception that children who have eclampsia sometimes become epileptic in after life, these accidental fits seldom or never merge into true epilepsy. The diagnosis of these cases must depend less on the phenomena of the attack than on their history and the circumstances which attend them—such as the presence of constitutional syphilis, the existence of renal disease, the fact that symptoms of cerebral disorder have been gradually creeping on before the convulsions attacked the patient, the evidences of abundant loss of blood, the progress of parturition, and the like.

In eclampsia due to the presence of tumours or other gross lesions of the brain, we have in its typical form that variety of the disease, known as ‘Jacksonian epilepsy,’ in which the character and localisation of the aura are determined by the functional attributes of the portion of brain involved, and indicate the site of the lesion. In this case it not unfrequently happens that the patient retains consciousness throughout the whole of his attack.

*Treatment.*—The treatment of eclampsia will depend mainly on the diagnosis at which we arrive: thus, syphilitic eclampsia will need to be treated with iodide of potassium and mercury; renal eclampsia will probably demand the use of powerful drastic purgatives; anæmic eclampsia will call for tonics, nourishment, and stimulants; eclampsia arising from accidental causes of irritation will require the removal of these causes; while that variety which is connected with progressive cerebral disease can only be treated by palliative measures.

### C. Infantile Convulsions.

*Definition and causation.*—These are seldom epileptic in the true sense of the term, and come therefore properly under the head of eclampsia. There are reasons, however, for giving a separate brief consideration to them.

Convulsions arise in young children, especially during the time of teething, with remarkable readiness and frequency; and indeed Dr. West observes that convulsions in children seem often to take the place of delirium or rigors in adults. It is certain that they are often developed in the course of diarrhœa and other disorders of the gastro-intestinal tract; that they occur in bronchitis and other affections of the respiratory apparatus; that they come on not only at the period of invasion of scarlet fever and other like diseases, but that they may be induced in the course of these disorders by various accidental circumstances; that they often depend on mere innutrition or anæmia; that they are common in rickety

children ; and that they are peculiarly liable to occur in connection with the irritation of teething. Children are, of course, liable, as adults are, to convulsions in the course of the development of tumours or other diseases of the brain or its meninges.

*Symptoms and progress.*—The convulsive attacks of children do not differ essentially from those of adults. They may be equally numerous, equally violent, and the 'status epilepticus' may equally be developed. They vary also in their intensity between the widest extremes. They do not, therefore, need any special description. Slight fits or threatenings of fits are very often indicated, either when the child is awake or when he is asleep, by sudden spasm of one or both hands with turning inwards of the thumb upon the palm, or by a momentary fixedness in the child's look, attended probably with pallor, dilatation of pupils, squinting, or some convulsive twitches of the face or limbs. It not unfrequently happens in children that the incidents of the fit are mainly connected with spasmodic contraction of the glottis and respiratory muscles. Respiration suddenly ceases, the face becomes livid and bloated, the veins swell, there is some rolling of the eyes, some convulsive movements of the muscles of the face ; then the head falls upon the chest, and the limbs become flaccid, the pulse gets feeble, quick, and perhaps imperceptible, bloody sputum issues from the mouth, copious sweats break out, and if respiration be not speedily restored death ensues. In some instances, such attacks are ushered in with a kind of crowing inspiration (laryngismus stridulus) ; in many they are perfectly silent. They are sometimes brought on during the continuous holding of the breath, or continuous expiration, which occurs when the child begins to cry, or when he is coughing or about to cough, and especially in connection with the paroxysmal attacks of hooping-cough. The number of fits which children suffer from and the frequency of their recurrence vary greatly. Sometimes the child has a single fit and never any more ; sometimes the fits recur many times a day, and the child may experience many hundreds of them in the course of a year. Not unfrequently, as before stated, he may pass into the status epilepticus and remain in that condition for some hours, or even a day or two. Infantile convulsions are always, and on good grounds, a matter for serious alarm ; it is astonishing, however, how children will suffer from almost innumerable fits, occurring off and on for months and years, and yet recover perfectly. On the other hand, they are often fatal. The most dangerous are those which chiefly implicate the respiratory organs, and those which by their rapid succession render the child comatose for a long period. The immediate cause of death is either suddenly or slowly induced asphyxia, asthenia, or coma. Fits often repeated have in some instances similar results to those occurring in adults : they are sometimes followed by hemiplegia or some other form of paralysis, or by failure of intelligence or idiocy. Stammering, squinting, and other such defects are sometimes attributed to fits in early life.

*Treatment.*—The child's general health must be carefully maintained or improved ; all affections, all causes of irritation which are present

must be removed. Bronchitis must be cured, diarrhœa checked, irritability of the stomach assuaged; if the gums are congested and swollen and the child is evidently suffering in consequence, they should be freely lanced, and the operation should be repeated whenever the indications of irritation return; if the child has been having unwholesome or insufficient food, or if he has been over-fed, these conditions must be obviated. The various specific modes of treatment are as applicable in the case of young children as in that of adults; and hence belladonna, bromide of potassium, antispasmodics, and other remedies have all been recommended, and in certain cases have been found serviceable. In the fit itself, there seems no reason to object to the ordinary practice of putting the child into a hot bath, and applying cold water, or a sponge dipped in cold water, to his head or face. Chloroform inhalations may also be had recourse to. Fits may sometimes be averted by applying ammonia to the nose, or cold water to the face, at the moment of their commencement, or when premonitory symptoms are heralding their approach.

---

## XVI. HYSTERIA

*Definition.*—It is difficult to describe, still more difficult to define, hysteria. It may, however, in general terms be said to be a functional disorder of the nervous system, occurring mainly in females from the age of puberty upwards, in which the will, the intellect, the emotions, sensation, motion, and the various functions which are under the influence of the nervous system, are involved, or apt to be involved, in a greater or less degree.

*Causation.*—As has already been stated in the definition of the disease, hysteria principally affects females and usually makes its appearance in them for the first time between the age of commencing puberty and that of five-and-twenty. It may come on, however, previous to puberty, and at any age after twenty-five; but in the latter case more especially about the time of the cessation of the menses. Males occasionally become distinctly hysterical; but there does not appear to be the same tendency in them as in women for the disease to come on in early life. The causes of hysteria, like those of so many other functional nervous disorders, are very obscure. There are two or three, however, which seem to have a very important influence, direct or indirect, in its causation; these are emotional disturbance, sexual conditions, and occupation.

Nothing is more certain than that hysterical phenomena and the hysterical fit itself are frequently induced by circumstances which affect the emotions powerfully, such as sudden fright or horror, powerful religious impressions, disappointed love or hope deferred, grief, jealousy, and the like. And indeed in those who are strongly predisposed to the affection the most trivial disturbances of this kind are liable to provoke violent outbreaks. Hysteria, like chorea and epilepsy, is often contagious.

The name hysteria was given to the disease under consideration in the belief that the womb was its seat. The fact that it occurs amongst men shows that that view of its origin cannot, at least in all cases, be correct. As regards females, however, there can be no doubt that the reproductive functions or organs do exercise a greater or less influence over its production. It comes on usually about the period of puberty or that of the climacteric change. Though not by any means occurring only in unmarried women, and those who are unhappily married, it occurs in them much more frequently than in such as become the happy mothers of families. And again in no inconsiderable number of cases there is distinct evidence of involvement of one or both ovaries in the facts that they are painful to pressure and that characteristic hysterical symptoms may be induced by applying strong pressure to them. There is, however, no necessary connection between the condition of the catamenial flow and hysteria, although it must be admitted that the catamenia are often at fault in hysterical women, and that occasionally their restoration to the normal condition is attended with the restoration of the patient's general health. Nor is there sufficient ground for believing that the mere default of sexual congress either in the male or in the female has, as a rule, any important influence in its causation; excepting perhaps in so far as it may be connected with the yearning for love, the sense of neglect, jealousy, and other such feelings. Sexual excesses, and especially masturbation, have been assigned as causes.

There can be little doubt that occupation and position in life have something to do with the production of hysteria, for it is a disease which affects the higher classes in a disproportionate degree; but if these conditions are concerned in its causation, it is owing to the accidental fact that wealth brings with it the needlessness for work and the capability of indulgence in frivolous amusements and idleness, with consequent neglect of the healthy exercise and discipline of the mind. Other causes which have been assigned for hysteria are hereditary predisposition, overwork, anæmia, debility, and other forms of failure of health; but any influence they may exert is at best remote.

*Symptoms and progress.*—In describing the clinical phenomena of hysteria we will first discuss the mental characteristics of those who suffer from it, and then consider *seriatim* the various motor, sensory, and sympathetic disturbances which are apt to be associated with them.

The *mental conditions* of hysterical patients present the greatest variety, and yet there are gradations between the extreme conditions which prove their relationship. In many cases women who are liable to hysterical attacks under occasional states of ill-health or excitement are in the intervals between their attacks as healthy in body and mind, and as free from all caprice or peculiarities of temper, as we could wish to see them. They will often acknowledge, however, that at the moment when hysterical feelings come upon them they feel compelled to yield to them and indisposed to make any effort to restrain them; and that yet if anything occurs to incite them to use self-control, they are able to resist them

successfully. In other cases the patient is nervous and excitable, with little control over either her emotions or her actions, apt to laugh or cry on the slightest provocation and incongruously, and apt also to suffer from time to time from the various complications of hysteria. But in a very large proportion of cases the whole moral character of the patient is profoundly altered. She is apathetic and neglectful of her duties, or exacting, selfish, and suspicious, exaggerating all her trivial annoyances and discomforts or disorders, resenting all healthy advice or reasonable attempts to promote her welfare, and quarrelling, therefore, it may be, with her husband or dearest friend, but pouring out profuse affection on all those acquaintances, however new they may be, who affect to pity her condition, make the most of her ailments, and adapt themselves to all her changing moods and caprices. Under such circumstances it is astonishing to see women, well nourished, and apparently in the best of general bodily health, remain for months and years useless members of society, suffering from paralysis and other maladies which they profess to look upon with the utmost alarm (and which they declare perhaps to be family complaints) not only with quiet complacency, but with a studied resistance to all plans of treatment likely to be of service to them. They are probably only too willing, however, to put themselves into the hands of some fashionable charlatan, or to do anything else which will render their misfortunes in any degree notorious. It is but a step from hugging her ailments and exaggerating them to malingering. And although we cannot fairly accuse the great majority of hysterical patients of shamming, shamming is by no means uncommon. The craving for pity and notoriety increases by being fed; the greater the commiseration she excites, the more does she endeavour to be worthy of it, and the more serious become the ailments from which she is suffering; and soon perhaps new phenomena develop. It is an interesting and important fact that the nature of these phenomena is not unfrequently determined by the direction which the interest and solicitude of the doctor or friends happen to take. If they pity her failing appetite, she soon perhaps affects to live without food; if it be observed that her urine and motions are scanty, she finds before long that they cease altogether; if it be a matter of wonder or speculation what becomes of her evacuations, she will be found perhaps to vomit urine or fæces, or blood. It is by such persons, though not by these alone, that various other singular forms of malingering are practised. Thus at one time a patient will bring on hard œdema or spurious elephantiasis of the arm or leg by the constant application of a ligature round the upper part of the limb, and will even submit to its amputation; at one time she will, by the constant application of some irritant substance, fret her skin into ulcers, and thus even cause perforation of the stomach; at one time she will place lumps of coal up her vagina and pretend that she is suffering from vesical calculus: at one time she will affect to have communion with the Virgin Mary, to have the marks of the stigmata on her hands and feet and side, and at the same time, probably, to live devoid of all those natural appetites and wants which are inherent in humanity. Hysterical patients

sometimes suffer from a form of insanity known as hysterical mania ; and occasionally after the lapse of years pass into a state of dementia.

We will now proceed to describe the various phenomena which are so apt to go along with the mental states which have just been considered, and which form, as a rule, the more striking phenomena of hysteria.

1. *Convulsions and spasms*.—Hysterical convulsions vary in their severity and duration, and have a more or less general resemblance to those of epilepsy, from which, however, it is important to distinguish them. The patient is rarely attacked without warning. She has probably, for some little time previously, been suffering from hysterical symptoms ; she has been laughing, crying, or sobbing, or talking wildly or gesticulating violently, or she has complained of a sense of constriction or of a ball in the throat, or has manifested in a marked way some of the mental or emotional phenomena which are characteristic of hysteria. Then suddenly, perhaps, she utters a loud scream, and falls upon the sofa or the ground violently convulsed. The fit may last for a few moments, or be prolonged for a quarter of an hour, or continued by successive attacks for many hours, interrupted from time to time by cries, and sobs, and laughter. Such phenomena generally also attend the subsidence of the attack ; or, if the patient be worn out with her long-continued exertions, she falls into a sound sleep. The main features by which the hysterical fit may be distinguished from the epileptic are the following :—the hysterical patient, no matter how severe her attack may be, is very seldom totally unconscious ; she can generally be aroused either by the voice of authority, or by a douche of cold water ; she is noisy—the epileptic utters a single cry, or none at all, while the hysterical patient probably screams and cries and laughs and groans or talks volubly and incoherently off and on during the whole of her attack ; her convulsions are much more general and extensive than those of the epileptic—she throws her arms and legs about in all directions, she twists her body into the most grotesque attitudes, she suddenly raises herself to the sitting posture, and then throws herself violently down again ; but with all this violence and excess of muscular effort she rarely, if ever, injures herself ; the convulsions are seldom tonic at any period of the attack ; they are rarely, if ever, unilateral, and the face (excepting when the patient is crying out) is free from the hideous distortion of epilepsy ; she does not bite her tongue ; the eyelids are closed and tremulous, but the pupils respond to light and there is no tendency to squint ; respiration never ceases, but it is from the beginning noisy and irregular, and consequently, although the skin may become hot and perspiring, the patient never presents that lividity of countenance which attends the true epileptic attack ; she does not discharge the contents of her rectum and bladder ; and lastly, if we investigate the history of the patient, we seldom find that she suffers from attacks resembling the *petit mal* or epileptic vertigo. Yet, though the distinction between epilepsy and hysteria is for the most part easy, instances are frequently met with (*hystero-epilepsy*) in which the hysterical attack puts on some of the features of epilepsy, or is even undistinguishable from it. It is then

attended with sudden and total unconsciousness, and it may be with tonic spasm, temporary arrest of respiration, lividity of face, biting of the tongue and involuntary discharge of urine and feces ; but even here the antecedent presence of the *globus hystericus* and other indications of hysteria, and the ultimate conversion of the attack into one of obvious hysteria, may suffice to render diagnosis easy. Charcot points out as a further distinction between these attacks and those of true epilepsy, that they never lead to impairment of the intelligence or dementia ; he further points out as an important distinction between the status epilepticus and the corresponding condition in hysteria, that in the former case the temperature rises to  $103^{\circ}$  or  $104^{\circ}$  or more, while in hysteria it rarely exceeds the normal by more than one or two degrees. But, though these distinctions generally hold good, they cannot be relied on absolutely.

Besides these general convulsive attacks, hysterical patients are liable to permanent or tonic contractions of groups of muscles or limbs. These, as will presently appear, are not unfrequently associated with paralysis. Among them may be mentioned closure of the hands, trismus, and contraction at the knee or other joints.

Other convulsive movements, sometimes associated with paralysis, sometimes independent of it, are also common in hysteria. In some cases patients are troubled with frequently-repeated spasmodic jerks of arm or leg, of both arms or both legs, of leg and arm of one side, or of some other part. Sometimes there are constant flickering movements about the angles of the mouth or the eyelids ; and fine tremors of the same kind are not unfrequent in limbs affected with rigid paralysis. Occasionally similar spasms are presented by the occipito-frontalis. These affections cease during sleep, but otherwise are apt to persist for weeks or months.

2. *Hyperæsthesia* is exceedingly common among hysterical women. It may be general, or hemiplegic, or paralegic, or it may affect a limb or a joint, the mamma or the ovary, the spine, or indeed any part of the surface, or any organ. Pain varies in its severity, is sometimes induced only by pressure, but often occurs independently of all external sources of irritation. It is a curious and suggestive, but not invariable, characteristic of it, that the patient will shrink from the slightest touch when she is expecting it, and yet will allow the painful part to be compressed and handled violently when her attention is directed to other matters. A common pain of which hysterical women complain is that which is termed *clavus* ; it is generally referred to the forehead just above the eyebrow, and is likened to the effect of a nail driven into the skull. The most interesting variety of hyperæsthesia, however, is that of which the *globus hystericus* forms a part. The *globus hystericus* is a sensation as of a ball rising into the throat and impeding respiration ; it is of frequent occurrence in hysterical patients, and is commonly present before and during paroxysmal attacks. It often seems to spring from the iliac fossa. The patient then complains of pain or tenderness on pressure in this situation, whence from time to time the hysterical aura, as it may be termed, seems to spread first to the epigastrium, causing nausea and vomiting ; then

to the chest, provoking violent action of the heart and palpitation ; then to the neck, constituting the globus hystericus, which is often associated with sobbing, choking, and other such symptoms ; and thence, finally, according to M. Charcot, to the head, when it induces noises in the ear, dimness of vision, and clonus, all on that side of the body from which the aura started. These phenomena constantly precede the occurrence of the hysterical fit, and, according to the older writers, with whom M. Charcot is completely in accord on this point, are referrible to some peculiar condition of one or other ovary, generally the left. He states : that in a large number of hysterical women there is a tender point which may be discovered on deep pressure made directly backwards at the point of intersection of the horizontal line drawn between the two antero-superior iliac spines, and the continuation downwards of the vertical line which marks the lateral boundary of the epigastrium ; that this point represents the ovary, which may in fact, when the abdominal walls are flaccid, be often distinctly felt in this situation ; and that continued pressure upon it will induce all the phenomena above described of the hysterical aura. This iliac or hypogastric pain varies in severity ; in many cases it can only be discovered by hunting for it ; but in many extreme pain and tenderness, so great as to forbid the slightest pressure, occupy not only the ovary but the superposed muscles and skin ; and occasionally these phenomena become so widely diffused as to simulate the local symptoms of peritonitis. Intolerance of light, intolerance of sound, and intolerance of certain sapid or odorous substances, often associated with extreme acuteness of the special senses, are common in hysterical women. But here again the phenomena generally present that marked characteristic of hysteria, namely, that the patient will complain bitterly of the slightest impression when her mind is directed towards it, but will endure the most discordant sound or the brightest light when her attention is distracted by other objects.

3. *Anæsthesia* is frequent among hysterical persons. It may occur in various parts of the body, and be limited to the distribution of a single nerve ; it may affect the sense of smell, or taste, or may implicate the eye. The most common cases are those of hemianæsthesia, with or without co-existing loss of motor power. In this variety the loss of sensation as a rule involves the whole of one side of the body—leg, trunk, arm, and head and neck—ceasing abruptly at the median line ; and it involves not merely the skin, but the mucous membrane of the mouth and the organs of sense, so that taste and smell are lost upon the affected side, and hearing and eyesight probably fail. The anæsthesia usually implicates not only the skin but also the deeper-seated tissues, namely, the muscles, bones, and joints. It may be complete and profound, or it may be mainly insensibility to pain, with or without insensibility to variations of temperature. The anæsthetic parts are usually normal of aspect and to feel, but are occasionally pale, relatively cold, and then, if pricked, less apt to bleed than healthy parts. The anæsthesia is liable to come and go, and to shift over from one side of the body to the other. Occa-

sionally it becomes universal. Not unfrequently hysterical patients present patches of anæsthesia, sometimes one or two, sometimes many, and either irregularly or symmetrically arranged. It is important to note that patients suffering from anæsthesia generally use the anæsthetic limbs as though there were nothing the matter with them, and rarely complain of their anæsthesia, so that it is left to the medical man to discover its presence. The senses of smell and taste are very often absent on the anæsthetic side of the body. They are sometimes lost on both sides, not only when there is cutaneous hemianæsthesia, but even when there is no cutaneous anæsthesia whatever. Tactile sensation of the lips and tongue is sometimes retained when taste is lost. Sight is often affected on the anæsthetic side of the body. Sometimes the patient perceives only a white mist, sometimes she loses in a greater or less degree the power of distinguishing colours or recognising the forms of objects, and generally the field of vision is contracted.

4. *Paralyses* are probably the most common of the complications of hysteria. Like anæsthesia, paralysis may affect any part; it may involve the hand, the forearm, the entire upper extremity; it may affect the leg or some part of it; in some cases it assumes the form of paraplegia, in some that of hemiplegia: or it may be irregularly distributed, or general. It seldom implicates the muscles of expression or the tongue. The paralysis may be complete or incomplete. The affected limb or limbs may be flaccid or rigid. The muscles usually do not waste, excepting from disuse; extreme atrophy, however, sometimes occurs. In the majority of cases hysterical paralysis may be distinguished from other forms of paralysis with tolerable readiness, but not always. If the paralysis be hemiplegic, it comes on probably after an hysterical fit; it involves the arm and leg, but neither the tongue nor the face; the affected limbs are probably rigid—the arm bent, the hand firmly closed; while the lower extremity, on the other hand, is extended—the toes pointed, and the limb and pelvis movable only in mass; it may be that the arm is flaccid while the leg is contracted, or conversely; the paralysis is probably associated with hemianæsthesia. It may be remarked that the hemiplegia of organic brain-disease is only occasionally associated with complete hemianæsthesia; that it is never attended with persistent rigidity from the beginning; and that if in this case there be any difference between the arm and leg in this respect, it is the arm and not the leg which becomes rigid. If the paralysis be paraplegic, the limbs are usually rigid and in a condition of extension; and the paralysis with rigidity is probably, as in the other case, suddenly developed. Whether the paralysis be hemiplegic or paraplegic, or limited to a limb, or part of a limb, it is apt to come and go, and to shift from limb to limb, or to involve more or less suddenly other limbs besides those first affected; and, above all, it is generally associated with other phenomena indicative of the presence of hysteria. It is, important, however, to recollect: that, although hysterical paralysis generally presents variations in degree, in character, and in site, it is (especially in its hemiplegic or paraplegic form) liable to continue for

years or for life; that the hand may remain clenched indefinitely, and that the foot may be extended and the toes flexed into the sole, as occurs in cases of organic nervous disease; and that although as a rule the muscles remain unaffected as regards their bulk and contractility, they may, in cases of long standing, undergo degenerative changes from disuse, in connection with which secondary lesions may also take place in the cord. Rarely the external muscles of the eye suffer; but occasionally we meet with hysterical paralysis of individual muscles, or even complete ophthalmoplegia externa.

5. *Affections of speech* are occasionally observed; more especially stammering (which is the more interesting that stammering is rare in women), and aphasia, which differs little if at all, excepting in its variability and temporary character, from that of organic disease. Sometimes the patient loses the power of uttering articulate sounds; not from inability to execute the necessary combined movements with her lips and tongue, but apparently because she is unable to co-ordinate the movements of articulation and those connected with the emission of air for the respiratory passages. Her lips move, but she fails to emit sound.

6. *Affections of the larynx and air-passages*.—Aphonia due to paralysis of the adductors and tensors of the cords is very common; the patient loses her voice completely and speaks only in the feeblest whisper; she probably, however, has no soreness in the throat, no difficulty or pain in swallowing, no evidence whatever of local disease. The voice, moreover, is generally feeblest when the patient is asked to display her powers; and sometimes reappears with sudden force under the influence of momentary excitement, or it may be of forgetfulness. Very rarely the abductors are paralysed, under which condition the patient retains her voice but suffers from inspiratory dyspnoea. This may be so great as to need tracheotomy for its relief. It usually, however, disappears during sleep. Attacks simulating those of ordinary asthma are occasionally observed. Not unfrequently a peculiar cough, which Sir Thomas Watson describes as ‘loud, harsh, dry, more like a bark, or a hoarse bleat, than a cough,’ is one of the special phenomena of hysteria; it is apt to come on in paroxysms, which may continue for hours without cessation, and may come on daily or nightly for weeks or months. In some cases without apparent cause, and with a pulse but little exceeding the normal rate, the respirations suddenly rise to 40, 50, 70, 80, or even 120 in the minute, and continue thus for some minutes, or on and off for hours or days, and yet without other evidence of dyspnoea or distress.

7. *Affections of the alimentary canal*.—In some instances patients suffer from well-marked trismus, which interferes seriously with both speaking and eating; occasionally they complain of difficulty of deglutition; and distension of the stomach, with rumbling and eructations, is of common occurrence. Hysterical patients often suffer from vomiting, and in some cases this constitutes the most serious part of their malady; the vomiting is apt to come on after every meal, or it may be at some

particular time of day, and to be continued day after day for months or years. This sickness is frequently associated with good or even voracious appetite; but the bulk of matters vomited often seems in excess of the ingesta, and after a time extreme emaciation and debility probably ensue. In some instances the symptoms almost accurately resemble those due to ulcer of the stomach. In a case of hysteria under care, occurring in a girl fifteen years of age, who had had hysterical hip-joint for three years, her other symptoms got complicated with vomiting after everything she took, and she became reduced to a skeleton. She was treated successively with milk in dessert-spoonful doses, then in tea-spoonful doses, and subsequently with pulp of raw beef in small quantities; but still she was sick, and from a few minutes to a quarter of an hour after deglutition vomited whatever she had taken. She was then fed only by enemata for some days; after which the feeding with milk in small quantities was resumed, but with the same result. It struck us at length that possibly the food never entered the stomach, but was retained in the œsophagus in consequence of spasmodic contraction of its lower part. We determined therefore to pass a tube, and to inject milk direct into the stomach. Three or four ounces were thus introduced, and they were retained. From that time forwards she swallowed without difficulty and was no more sick. The bowels are usually constipated, and there may be pain in defæcation. Symptoms, difficult if not impossible to distinguish from those of acute idiopathic peritonitis, seem occasionally to be of hysterical origin.

8. *Affections of the urinary organs.*—Retention of urine often occurs. Doubtless it sometimes depends on paralysis of the bladder, contraction of the sphincter, or pain in the act of micturition; but not unfrequently, like most other hysterical conditions, it is more or less within the control of the patient, who makes no attempt to relieve herself voluntarily so long as she can enjoy the morbid pleasure of having the catheter passed for her. But more interesting than this are the phenomena connected with the secretion of urine. It usually happens, after an hysterical fit, or after other paroxysmal nervous disorders, that the patient excretes large quantities of pale limpid urine. And such profuse discharges are not unfrequent at other times. But the opposite condition may be present. The patient consecutively for many days does not pass more than a few ounces of urine. In a remarkable case published by M. Charcot, the sufferer, a woman, forty years old, for more than a couple of weeks passed every other day only five grammes of urine, and none on the intervening days, and for a continuous period of ten days secreted no urine whatever. During one month her average daily yield was only three grammes, and during another month only two grammes and a half. In this case the diminution and suppression of urine were unconnected with renal disease, but were associated with constant vomiting, the quantity of fluid vomited having some supplementary relation to the quantity of urine voided. Further, the vomit contained urea, yet the urea secreted daily by the kidneys and stomach together was very far indeed below the

normal. For a period of twelve days it amounted from both these sources to only five grammes daily. M. Charcot remarks, in reference to such cases, that the escape of even a small quantity of urea in calculous obstruction of the ureters often serves to ward off dangerous symptoms, and that doubtless the same rule applies here; but he further observes that there is probably in hysterical ischuria an impairment of the functions of assimilation which diminishes the total amount of urea and extractives to be discharged from the body.

9. *Of affections of the reproductive system* little remains to say beyond what has already been said. Amenorrhœa, menorrhagia, and other menstrual disorders are no doubt frequent accompaniments of hysteria; but many hysterical women are quite free from them. Again, the hyperæsthesia which is so common in various parts of the body in hysteria may affect the vulva or vagina and render the act of coition intolerable; whilst, on the other hand, lascivious feelings are occasionally strongly developed, and either induce in the patient a demeanour, probably towards certain individuals, which far transgresses the bounds of womanly self-respect, or give a motive for feigning disease of the sexual organs. It is not surprising that the mental obliquity of such patients should occasionally incline in this direction.

10. *Other affections* which hysterical patients are apt to mimic are those of the *spine*, of the *joints*, and of the *mammæ*. These have already been adverted to under the head of hyperæsthesia. They often closely simulate inflammatory disorders of the same organs and are apt to be mistaken for them; but, on the other hand, we must not hastily assume that a suspected hysterical affection of these parts is not hysterical because we discover swelling in addition to pain and tenderness.

11. *Hysterical fever*.—Occasionally hysterical patients present febrile rises of temperature which are obviously not due to any inflammatory process, and which are doubtless primarily neurotic, and in this respect resemble other hysterical phenomena. The temperature, as Dr. Hale White shows, is apt to be erratic, and also to reach a high elevation. It is possible that some of the cases of extreme hyperpyrexia which have been observed in females, and which have usually been regarded as factitious, were of this character. In two cases of functional, and in a sense therefore hysterical, disease in women which were under our own care, such high temperatures, independent of inflammatory processes, were a striking and persistent phenomenon. In one, for more than two years the temperature varied daily from the normal up to  $102^{\circ}$  or  $103^{\circ}$ ; and in the other, for nearly an equal length of time, the temperature invariably rose gradually to between  $102^{\circ}$  and  $105^{\circ}$  during the day or two preceding periodical convulsive attacks to which she was liable.

12. *Spinal irritation* is the name given to a group of hysterical phenomena which have been particularly described by Mr. Teale and the Messrs. Griffin, and is still by many regarded as a distinct affection. It is characterised by the presence of tenderness at some spot in the course of the spine, or more rarely generally throughout its whole length, and by

pain or other nervous phenomena referred to those parts of the body whose sensory nerves are in relation with the tender spot, or to certain of the viscera. Moreover, pressure upon the tender spot aggravates, or it may be actually induces, the phenomena in question. If the tenderness occupy the upper part of the cervical spine, the neuralgic pain associated with it affects the occipital region, or it may be even the distribution of the trifacial; if it be a little lower down, the neck suffers; if it occupy the situation of the cervical enlargement the pain is experienced mainly in the arms; if it be present in the dorsal region then the parietes of the chest or abdomen suffer; if it implicate the lumbar enlargement, the pelvis and the lower extremities are the chief seats of pain. Further, the sensation of a lump in the throat, palpitation, dyspnoea, spasmodic cough, gastralgia, nausea and vomiting, irritability of the bladder, suppression of urine, are all apt to attend the spinal tenderness; but the particular group of these complications appears to be determined, like the neuralgic pains, by the situation of this tenderness. In all respects besides those which have been enumerated, the symptoms which the patients present are identical with those of other forms of hysteria, and indeed the phenomena of these affections are, if not common to both, inextricably interwoven. The course of the disease, moreover, is identical in all respects with that of hysteria.

The *diagnosis* of hysteria is not always easy; and yet if the patient be carefully watched from day to day it is difficult to remain very long in doubt. It is not, however, an unnecessary caution to remind the reader that not only does hysteria ape many diseases so as to be readily mistaken for them, but that other diseases often simulate the phenomena of hysteria and may be easily taken for it. There is always a great temptation to assume that nervous disorders which we do not understand, and obscure visceral affections, in females are hysterical. Among diseases which may thus be mistaken for hysteria should especially be named chronic inflammatory conditions of the brain and cord, and tumours of the brain. In forming a diagnosis we must carefully consider all the features which the special affection from which the patient suffers presents, and how far and in what respects they differ from those of lesions of the same parts which are not of hysterical origin. We must also look carefully to the various complications which attend the main affection, or which supervene from time to time, or alternate with it; for it rarely happens that a patient, suffering from an hysterical joint or from hysterical hemiplegia or paraplegia, does not also at one time or another have an attack of aphonia, or retention of urine, or a bout of intermingled laughing and crying, or a distinct hysterical fit, or that the original affection does not undergo some striking change, or shift to some other part. We shall often be importantly aided in coming to a decision by careful observation of the demeanour and conduct of the patient, and of her general tone of thought and feeling. It may be added that in hysterical paralysis the reaction of the muscles to faradism and galvanism either remains normal, or shows general slight diminution only; and in the latter case generally becomes normal after a

brief application of electricity. The reactions of degeneration are never observed. Electrical sensibility of the muscles is generally lost in these cases. The tendon reflexes are probably always retained. They are sometimes exaggerated and there may even be ankle or knee clonus. The superficial reflexes, especially the plantar reflex, are often absent.

Hysteria is very common ; and varies from a slight affection of little importance to one of such gravity that it renders the patient a lifelong invalid, and her existence a burden and a misery to herself and those about her. Fortunately the milder cases are by far the most common ; and in many of these complete recovery takes place, while in many recovery is so far complete that there only remains a liability to the outbreak of slight hysterical phenomena under special circumstances of ill-health or excitement. Not unfrequently, however, patients suffer from hysterical vomiting, alternating, it may be, or associated with other hysterical symptoms for years ; or they remain hemiplegic or paraplegic and bedridden for one, two, ten or twenty years ; or they suffer from urinary disorders, or aphonia, or joint-affections for an equally indefinite period ; or they are the victims of constantly recurring violent fits. In some cases patients continue thus for life. It may be said generally that the longer the phenomena have persisted, the less likely is ultimate recovery to take place ; but it must never be forgotten that (unless any organic complication has arisen) there is always a possibility that the patient will get well, and not only get well, but get well suddenly. The patient who has been confined to her bed paralytic for years will perhaps, under the influence of some sudden impulse or mental or emotional excitement, recover the complete use of her limbs ; the patient who appeared doomed to lifelong voicelessness will suddenly speak aloud in her natural tone.

*Pathology.*—We do not pretend to give any account of the morbid anatomy of hysteria or of its pathology. On these heads little or nothing of any importance is known, and we do not care to speculate. It is, so far as we know, a purely functional disorder.

*Treatment.*—The treatment of aggravated hysteria is exceedingly difficult, and all the more difficult that the patient's condition excites in those about her that sympathy which she craves ; and that consequently that judicious firmness of management which the medical man should exercise is apt to be resented not only by herself but by her friends. Nothing, indeed, is more injurious to such patients than the pity and attention they receive ; they live for them, they lay their plans to attract them, and their moral and bodily condition deteriorates under their influence. On the other hand, the exercise of a judicious firmness is essential for their successful treatment ; and this it is impossible for the medical man to accomplish unless he acquires the confidence, if not of the patient, at all events of those under whose control she is. For this purpose it is not necessary to be harsh, indeed harshness is likely to defeat its object ; but the respect, and if possible the trust, of the patient should be acquired by the cultivation of kindness and friendliness of manner with firmness of purpose. There should be on the part of the doctor a judicious blending

of the 'suaviter in modo' with the 'fortiter in re.' No doubt hysterical patients are extremely disposed to exaggerate their symptoms. No doubt they do occasionally wilfully and grossly deceive those about them. But it must not be assumed that there is generally intentional exaggeration, still less that there is imposition. They do, as a rule, really suffer that of which they complain, and suffer more when their attention is directed to the ailing part. It is impossible in a brief space to lay down any rules with regard to the general treatment of these cases. No doubt it is important to improve the general health, to relieve dyspeptic symptoms, to cure anæmia, to regulate the catamenia, to see that the bowels act properly, to insist on regular hours, good wholesome diet, and daily exercise, and it may be to order change of air and scene; especially it is important to make the patient take an interest and pleasure in some useful occupation or some intellectual recreation or study. But it must never be forgotten that, to use Sir Thomas Watson's words, 'behind the moody, reserved, and tricky behaviour there often lies some mental or emotional cause—some hope deferred or disappointed—which being ascertained, and capable of satisfaction and satisfied, the patient may be restored to her customary health.' Dr. Weir Mitchell has proposed, and practised with success in severe cases, and especially in cases characterised by loss of appetite, refusal of food, and emaciation, a plan of treatment which combines moral influence and physical measures: the most important factors being the enforcement of absolute rest of mind and body, regulated passive exercise of the muscles, and abundant feeding. To carry out the plan effectually the patient should be wholly separated from her friends and home, and placed under the sole charge of a competent nurse; her muscles should be well shampooed by a skilled rubber for two or three hours daily, and also well faradised once or twice a day for ten, fifteen, or twenty minutes at a time, and her diet should rapidly be increased in amount until she takes perhaps two or three times as much food as a healthy person would do. The course of over-feeding is usually preceded by several days of under-feeding. A few weeks are generally needed to effect a cure.

Among the drugs which have been employed with more or less success, or want of success, may be especially mentioned iron, zinc, vegetable tonics, assafoetida and other fetid gum-resins, and stimulants. Alcohol in various forms is often recommended by the medical attendant or had recourse to by the patient; but alcoholic beverages, chloral, opium, and other narcotic medicines, should be given or allowed with extreme caution, for the temporary relief which they give is very apt to lead to their habitual use and ultimate abuse. In the hysterical paroxysm very often nothing more is needed than to lay the patient down and unfasten her dress or anything tight about her neck; it may, however, frequently be cut short or prevented by the free use of cold water—by dashing it in quantity over the neck and face—or, as Dr. Hare points out, by firmly closing the patient's nose and mouth for a time, or until her dyspnoea is such that she is compelled to draw a long breath. Less valuable than these measures,

though not altogether to be despised, are the inhalation of sal-volatile or smelling salts, and the exhibition of ammonia, assafoetida, or ether.

M. Charcot, besides pointing out the readiness with which hysterical paroxysms may be induced by pressure made in the region of one of the ovaries, shows that in the same cases powerful, regulated, and sustained pressure is generally efficacious in arresting the paroxysm, however violent it may be.

The removal or relief of the various local phenomena of hysteria frequently demands special forms of treatment; aphonia may generally be cured by faradism of the throat, effected either by placing one pole of the instrument within the throat and the other external to it, or by placing the poles on either side externally. Paralytic affections are largely benefited by the same treatment, or by the frequent use of the cold douche. Dr. Reynolds specially recommends the application of narrow strips of blister round the affected limbs. Anæsthesia also is sometimes remediable by faradism. But for this, especially if there be at the same time coldness of surface and imperfect circulation, as also for the cure of hysterical contractions, galvanism is probably preferable.

It is mainly in cases of hysterical anæsthesia that Dr. Burq's<sup>1</sup> metallo-therapeutic treatment has come into vogue. This consists in the local application of some metal to which, by experiment, the patient is found to be sensitive. The metals employed are gold, silver, iron, copper, and zinc. To ascertain which of these is appropriate, discs of each must be applied in succession for two or three minutes each to the region about to be operated upon. This point having been determined, bands or groups of discs of the selected metal must be kept for a quarter of an hour or so in close contact with the affected surface by a bandage or other means. It would appear that the result is that the affected part (whether it be the skin or organ of special sense) gradually recovers its sensibility, and that associated with this there is a return of warmth and circulation, and of muscular power. But it would also appear: that whatever improvement there is on the one side of the body is at the expense of the opposite side, which becomes anæsthetic in proportion as the other recovers: and, moreover, that the recovery is only temporary.

The sudden cure of hysteria in any of its forms is almost always possible under the influence of powerful emotional excitement. Thus a sudden alarm that the house is on fire will sometimes cause a woman who has been paraplegic for years to rush from her bed with the full use of her limbs; the unexpected infliction of sudden and severe pain generally suffices to make the dumb cry out at the top of her natural voice; the promise that if a long-closed hand opens by a certain day it shall have a valuable trinket placed in it generally calls for fulfilment.

---

<sup>1</sup> See report by MM. Charcot, Luys, and Dumontpallier, quoted in the *British Medical Journal*, May 19, 1877.

## XVII. CATALEPSY, ECSTASY, SOMNAMBULISM, AND OTHER CONDITIONS ALLIED TO HYSTERIA

A large number of curious nervous phenomena—motor, sensory, emotional and intellectual—occur, which are difficult to describe save by the help of illustrative cases, difficult to classify, and difficult to attach to specific lesions or specific conditions of the nervous system. In a large proportion of cases they originate in powerful mental excitement, and more especially in such as is connected with religious fervour; they sometimes also arise from imitation or moral contagion. Young persons, from the period of commencing puberty to the termination of adolescence, and more particularly females, or males of emotional temperament, chiefly suffer. The patients are often distinctly hysterical; and not unfrequently hysterical paroxysms and some of the various other phenomena which have been considered under the head of hysteria complicate some of the conditions we are now about to describe, or alternate with them. Indeed, if we look to the exciting causes, to the class of persons who are most commonly affected, to the character of the symptoms, and to their frequent association with hysterical phenomena, we can scarcely avoid regarding the affections under consideration as varieties of hysteria. We believe that they generally are so. In some cases, however, they seem to be related rather to chorea, epilepsy, or insanity.

1. *Rhythmical and other methodical movements.*—These present innumerable varieties of character. In some cases the patient performs unceasing oscillatory, undulatory, or rotatory movements of the head and neck, or of the entire trunk. In some she is seized with an uncontrollable impulse to run forwards or backwards. In some she is impelled from time to time to leap into the air. To the same class must be referred the violent rhythmical movements which attended the ‘dancing mania’ of the Middle Ages.

2. *Catalepsy.*—By this term is meant an attack of loss of sensation and of consciousness, attended with remarkable stiffening of the muscles. The patient for the most part is attacked suddenly, after mental or emotional disturbance; she becomes pale and corpse-like, the respirations being slow and tranquil, the pulse soft. She cannot be roused, and is entirely insensible to pain. But the most striking phenomenon is the stiffness of the muscles, which is such that the limbs, head and neck, or features, when forcibly put into any position, however constrained and unnatural it may be, or however difficult to be supported by the healthy muscles, retain that position for some length of time. But although the patient appears to be unconscious of external impressions, and to remember nothing of what happens during the attack, she will sometimes sing or talk whilst it is upon her, or indicate by her expressions the presence of pleasing or painful impressions. A cataleptic condition may also occur in patients who still retain full consciousness. Cataleptic attacks may last from a

few minutes to several days ; there may be a single attack only ; or they may recur with more or less frequency.

3. *Ecstasy* is a condition in which the patient is absorbed in some all-engrossing fancy or delusion. It is the condition to which weak-minded persons are wrought under the influence of revivalist preachers, and in which they are sometimes impelled to plead frantically for pardon for imaginary misdeeds, are sometimes in a delirium of complacency and joy at their supposed enrolment among the saved. It is the state into which those persons fall who believe that they see visions of Christ, of the Virgin Mary, of saints, or of angels, or who hold familiar intercourse with them, or who receive divine messages. It is the state into which the medium is not unfrequently brought under the mesmeric influence. It represents also the mental condition of the dancing maniacs of the Middle Ages. The nature of the fancies or delusions under which such patients labour may, therefore, present the widest range of variety, and their effects on the mind all degrees of intensity. Their influence over the actions of the patient, moreover, is very various. Thus, while one will gesticulate violently and roar or scream his prayers or denunciations, another will dance or sing or utter pious ejaculations ; another will sit apart with an air of self-satisfaction or quiet happiness ; and yet another will be transfixed or stunned, as it were, with intense anxiety or horror. In some of these cases the patient remains motionless and apparently insensible to every external impression for days together. But generally they are not wholly insensible ; and although the mind may not be capable of being diverted from its engrossing thoughts, the pupils contract and the eyelids close under the influence of a strong light ; sneezing and watering of the eyes may be induced by the application of ammonia or snuff ; and the respiratory muscles may be made to act powerfully under the shock of a jugful of cold water.

4. *Somnambulism*.—Other curious mental states, allied to those described in the last paragraph, are occasionally observed in persons who are either distinctly hysterical or of emotional temperament. Sometimes such patients pass into a dreamlike state, or one of apparent unconsciousness, during which automatically they ramble about for hours, or act in a strange and unaccountable manner, much as epileptics do, retaining, on coming to themselves, little if any knowledge of what they have been doing. In some instances during their attack they laugh and sing and chatter, in rapid sequence, and more or less incoherently ; and in one case, which came under our observation, the patient, a young girl, was in the habit of repeating with much volubility the conversations she had overheard or taken part in during the day. Cases also have been recorded of persons who, while thus affected, have performed surprising feats of memory, of which in their waking state they were wholly incapable.

Occasionally the patient appears to live, as it were, a double life—the one her normal state of existence, in which she is fairly sensible, and knows and understands, and perhaps takes an interest in, everything that goes on about her ; the other a state of ecstasy or somnambulism, in

which her mind is under the dominance of delusions, and in which the same lines of thought and feeling and the same delusions are continued through the successive ecstatic paroxysms; and in neither of which has she any recollection or knowledge of what occurs in her alternative condition. Occasionally these strange phenomena may be prolonged for years, the one state passing into the other almost suddenly several times a day. The waking condition, indeed, may form but a small portion of her existence, and may itself be attended with curious motor, sensory, or mental phenomena.

5. Two remarkable cases of functional nervous disease in women have come under our care, which presented groups of so many unusual symptoms and so many symptoms in common, that they might seem to be examples of a type of disease not hitherto described, and at any rate merit a brief description. The patients were young, and in both the symptoms were progressive, although the order of sequence presented some differences. In the fully-developed stage of their disease they presented complete ophthalmoplegia externa, anæsthesia of one side of the body with loss of taste and smell (and in one, colour-blindness) on the same side, hemiplegia with rigidity, headache, vomiting, and periodical fits which were undistinguishable from those of epilepsy. Moreover, in both cases there was a prevalence of high temperature without any inflammatory lesion to explain its occurrence. In one the temperature rose every day from  $2^{\circ}$  to  $5^{\circ}$  above the normal. In the other it rose only during the day or two preceding her fits, and fell suddenly to the normal with their onset. Its highest elevation varied between  $102^{\circ}$  and  $105^{\circ}$ . The one patient died of an accidental attack of bronchitis, and no disease whatever was discovered in her brain or cord. The other recovered and remains well. In both cases the patients were ill for two or three years.

*Treatment.*—In treating the various cases which have just been considered it is important not to lose sight of the fact of their intimate relations with certain other nervous diseases, more especially epilepsy, hysteria, and insanity, of which indeed, in the great majority of cases, they may be regarded as mere varieties. Their treatment, therefore, resolves itself mainly into the treatment of these affections. Everything calculated to improve the general health of the body is indicated; but if a cure is to be effected it is rather by judicious management than by medicines.

---

## XVIII. TETANUS. (*Trismus. Lockjaw*)

*Definition.*—Tetanus is an acute and generally fatal disorder, characterised by painful tonic spasms of the voluntary muscles, and usually traceable to some local injury.

*Causation.*—Tetanus may originate in a trivial graze of the skin, the wound inflicted by a mere splinter, or a clean cut. But it far more commonly follows on compound fractures or other injuries attended with

laceration or crushing. It is generally believed that injuries of the extremities are much more liable to be followed by it than injuries of the head and neck or trunk; but, as Mr. Poland justly remarks, the limbs are far more prone to accidents than other parts, and it is probably on this account alone that their wounds are credited with a disproportionate proclivity to tetanus. But climatic conditions also are concerned in the production of tetanus; for the disease is much more common in hot than in cold or temperate climates; and although it so often supervenes on wounds received in battle, it occurs more frequently when the wounded are exposed to cold and wet than under opposite circumstances. Indeed a form of the disease, occurring apparently independently of any breach of surface, is usually referred to the influence of these latter agencies—agencies which also induce rheumatism, pneumonia, and other internal inflammations. Tetanus may occur in either sex, and at any age. In the West Indies it is very common in new-born children, in whom it is supposed by some to be due to the division of the umbilical cord; and it occasionally happens in women after parturition.<sup>1</sup> Tetanus has long been suspected to be contagious, but has only recently been proved to be due to a specific form of bacillus and to be inoculable. This bacillus is about the size of, but more slender than, the septicæmic bacillus of mice, and is described as pin-like in form, owing to the presence of a comparatively large spore at one of its extremities. It appears to abound in many kinds of soil, in street dust, and in the sweepings of floors; and it has, when carefully looked for, constantly been found in and about the wounds or seats of inoculation in tetanic patients, and occasionally been found in nerves leading thence to the cord itself and elsewhere. That the bacillus is the cause of tetanus is proved, not merely by its unfailing presence in cases of tetanus, but especially by the fact that the inoculation of rabbits and guinea-pigs with earth or dust containing it, with the morbid tissues or the blood of patients suffering from tetanus, or with the cultivated bacillus, is, with few exceptions, followed by tetanic symptoms. Several poisonous substances have been obtained from the bacilli of tetanus, which in sufficient doses are themselves capable of inducing tetanoid symptoms; a fact which tends to confirm the view that micro-organisms produce deleterious effects, not by their simple presence in the tissues, but by some poison to which they give origin. Indeed it is suggested by Giordano that the symptoms in tetanus are due to the absorption into the system of poisons generated by the bacilli resting in and about the primary lesion.

*Symptoms and progress.*—Tetanus comes on after injury at periods varying between a few hours and three or four weeks—most commonly, according to Sir T. Watson, between the fourth and fourteenth day. When the disease is due to exposure, it always supervenes very quickly—occasionally in the course of a few hours.

<sup>1</sup> The first discoverers of the bacilli of tetanus were Nicolaier and Rosenbach, whose observations have been confirmed by the later investigations of Flügge, Beumer, and others. See paper by N. Senn, M.D., *Transactions of the American Surgical Association*, vol. vi. 1888.

The first symptoms of which the patient complains are usually pain and stiffness of the muscles of the jaws and neck—symptoms which he probably refers to cold, and describes as sore-throat and stiff-neck. He has difficulty in opening his mouth, in masticating, and in moving his head, which is soon followed by dysphagia, and by spasmodic attacks of pain and aggravation of his difficulties, provoked especially by every attempt to use the affected muscles. By degrees the stiffness and tendency to painful spasm extend to the other voluntary muscles: to those of the back, which by their action on the trunk tend to curve the body backwards: to the inspiratory muscles, especially the diaphragm, the implication of which involves difficulty of respiration, and occasional attacks of more severe dyspnoea, attended with acute pain striking through from the ensiform cartilage to the interscapular region; to the muscles of the abdomen, which get rigid and knotted; to those of the extremities, which become difficult of flexion, and from time to time powerfully and violently extended; and to those of expression, which by their tonic contraction impress upon the patient's features a fixed painful look (the *risus sardonicus*), which becomes intensified during each recurring spasm. The muscles of the tongue and eyeballs, and those which move the hands and feet, usually escape or are involved late and to a slight extent only.

As the disease progresses all the implicated muscles become stiff, and the stiffness gradually increases. But from the beginning the patient is liable to paroxysmal attacks, during which all his symptoms are enormously aggravated, and which come on at irregular but diminishing intervals: sometimes every quarter of an hour, sometimes every ten or every five minutes, and last individually from a few seconds to several minutes. These occur for the most part spontaneously, but are readily induced by any muscular effort, by moving the patient, or even by the slamming of a door and other such-like trivial causes.

In the fully developed disease the patient, during the inter-paroxysmal periods, probably lies stiff in bed upon his back. The muscles of the trunk, limbs, and neck are hard and rigid; the jaws cannot be opened at all, or admit of being separated only to the extent of a few lines; the face wears a painful expression, the brows being knit and at the same time transversely wrinkled, the eyes somewhat closed, the angles of the mouth drawn outwards and upwards, the lips apart, and the grooves extending from the alæ of the nose towards the angles of the mouth deepened; the mouth and fauces are clogged with saliva, which he has difficulty in swallowing; the voice is feeble, possibly reduced to a whisper; and the respirations are rapid and shallow. Further, he probably complains of general pain or soreness, and especially of pain extending from the scrobiculus to the back. During the paroxysms his sufferings become extremely aggravated, and frightful to witness. His arms and legs (especially his legs) become more powerfully extended, and at the same time widely separated: the extensor muscles of the spine arch the trunk and head and neck powerfully backwards, so that not unfrequently the patient

rests only on his head and heels; the respiratory muscles get more or less fixed, respiration difficult, and the face pale, livid, or ghastly; the distortion of the features, moreover, is now extreme—the forehead corrugated by the combined action of the frontales and corrugators, the eyeballs fixed and staring, the eyelids rigid and partly closed, the nostrils dilated, and the angles of the mouth drawn outwards and upwards so as to impart that peculiar appearance of grinning which has been referred to. The lips moreover are retracted, exposing the clenched teeth; between which bloody saliva occasionally flows in consequence of the accidental wounding of cheek or tongue by their sudden closure at the commencement of the paroxysm. The paroxysms are said frequently to come on with increase of the diaphragmatic pain; and during their continuance cramp-like pains of the most agonising character pervade the contracted muscles.

Certain other phenomena to which it is desirable to draw attention present themselves in the course of tetanus. The pulse is for the most part rapid and feeble, and its rapidity and feebleness increase with the progress of the case, and are especially observable during the paroxysms. At such times also the skin, which is generally moist or perspiring, breaks out into profuse sweats. The urine is for the most part scanty, and the bowels are constipated; but the patient has entire control over bladder and rectum. According to Dr. Senator, there is no increase of excretion of the urinary solids. In the great majority of cases the patient retains his senses unimpaired throughout his illness, and is conscious up to the moment of death. He seldom sleeps, or he sleeps only by snatches. Sometimes the spasms cease entirely during sleep. The temperature in tetanus is generally somewhat above the normal, and liable to irregular diurnal variations. It does not usually exceed  $100^{\circ}$  or  $101^{\circ}$ , but may rise from time to time, even in cases which ultimately do well, to  $102^{\circ}$ ,  $103^{\circ}$ , or more. Nevertheless, when the temperature reaches or exceeds  $103^{\circ}$ , the symptom must be regarded as of serious import. Occasionally, with the approach of death, the temperature rises rapidly, and it may then attain an elevation of  $110^{\circ}$  or even  $112^{\circ}$ . Sometimes in the course of tetanus the temperature becomes sub-normal.

When the tetanic spasms affect only or principally the muscles of the jaw, the effect is often termed *trismus* or *lockjaw*. When, as usually happens, the body during the tetanic spasms is arched backwards, the condition is termed *opisthotonos*. In those rare cases in which, owing to the predominant action of other muscles, the body is curved forwards or to one side, the condition of *emprostotonos* or *pleurostotonos*, as the case may be, is present.

The prognosis of tetanus is very gloomy; almost all traumatic cases, and the great majority of idiopathic cases, die. According to Mr. Poland, taking all forms together, the mortality is at the rate of about 88 per cent. The most rapid cases, according to the same writer, die in four or five hours. But death has been delayed until the thirty-ninth day. More than half the total number of fatal cases perish during the first five days. Death is usually caused either by asthenia, by asphyxia, or by a combina-

tion of these conditions. It not unfrequently occurs suddenly in one of the spasmodic attacks, and is then probably due immediately to spasm of the respiratory muscles, and possibly to those of the glottis.

Tetanus may be simulated by hysteria, by inflammatory affections of the spinal cord, and especially by the effects of strychnia and other allied drugs. As regards the first two classes of disease, there can seldom be any real difficulty in distinguishing between them and tetanus, in consequence in the one case of the supervention of paralysis or other signs of organic lesion of the cord, in the other case of the association of various hysterical phenomena with the spasmodic muscular rigidity. Strychnia-poisoning, on the other hand, may be readily confounded with tetanus. The chief distinction between them lies (to quote Dr. Christison's words) in the fact that 'the fits of natural tetanus are almost always slow in being formed, while nux vomica brings on perfect fits in an hour or less.' Further, tetanus rarely, if ever, 'proves so quickly fatal as the rapid cases of poisoning with nux vomica.' It need scarcely be added that the history and etiology of all cases in which tetanic spasms are present should be investigated with minute care.

*Morbid anatomy.*—Various lesions have been discovered in the nervous system. In traumatic tetanus the nerves proceeding from the injured region have been found swollen, hyperæmic, and inflamed, either in part or in their whole length. In many cases, however, no such lesions have been perceived. It was formerly believed that the spinal cord was healthy; but recent investigations, and more especially those of Drs. Lockhart Clarke and Dickinson, have demonstrated the presence, in some cases at least, of considerable dilatation of the small vessels (particularly the arteries and veins) with accumulation of blood within them and around them, together with more or less abundant translucent or finely granular exudation, infiltrating the tissues, and tending to accumulate here and there, especially in the fissures, and occasionally on the surface, of the cord. With these changes are associated sometimes disintegration of the proper nervous elements, sometimes local effusions of blood. In trismus neonatorum congestion of the spinal arachnoid is described, with effusion of serum and even extravasation of blood into the subarachnoid tissue. It can scarcely be admitted, however, that these lesions are proved to be invariably present in tetanus. That the motor nuclei of the spinal cord and medulla oblongata are generally in a state of polarity or abnormal irritability, or that they are generally under the influence of some abnormal condition which excites them to unwonted action, is clear enough. But whether this excited action is due to some peculiar change in the nerve-cells themselves, or to the influence exerted upon them by the congestion and effusion which surround them, or to the presence in the blood of some endopathic poison (as is suggested by Sir T. Watson and by Dr. Richardson) resembling strychnia in its effects, are now mere barren speculations, since, as we have already shown, tetanus depends on the specific influence of living parasitic organisms. Ruptures of muscular fibres are frequently seen after death from tetanus. They are common in

the muscles of the back, but sometimes occur in the abdominal muscles and those of the extremities.

*Treatment.*—No treatment, so far as we know, has any curative influence over tetanus. A certain number of cases get well under the most unfavourable circumstances; the great majority die in spite of the most strenuous efforts to save them. Innumerable drugs have been employed, and, according to their several advocates, with more or less success. Among those which have acquired the greatest reputation are opium, mercury, wourara, Calabar bean, and chloroform. Many other medicines, for the most part sedatives, have also been recommended, especially, perhaps, aconite, belladonna, digitalis, tobacco, hydrocyanic acid, chloral, and turpentine. By some authorities, drastic purgatives have been lauded; by some, profuse stimulation by means of ether or alcohol. It is important to know that tetanic patients can take large doses of the most powerful sedative medicines and drink large quantities of alcoholic beverages without being brought under the influence of these agents. Warm baths, cold baths, ice to the spine, bleeding, division of the nerves leading to the injured spot, and even amputation of the limb or part on which the injury was inflicted, are measures which have each in turn been adopted and abandoned.

As regards general rules of treatment we cannot do better than quote Sir T. Watson's words. He says:—'Since any, the smallest, movement or impression made upon the surface, or upon the senses, will bring on the severer degrees of spasm, it is of primary importance to protect the patient against those sources of trouble, so sure to aggravate his sufferings, and so likely to augment his danger. Hence, if blood-letting should be thought advisable, it should be done early, sufficiently, and once for all.' 'The same remark applies to the frequent use of purgatives. The bowels should be well cleared at the onset, and then let alone. The patient should lie in a darkened room, from which noise also should, as much as possible, be excluded. He should not be surrounded by a multitude of friends or attendants. He should be enjoined to speak, to move, to swallow, as seldom as he can. In the severe traumatic cases, the nerve, in my judgment, should be promptly divided, and as high up in its course as may be practicable; and in all cases, there being no special indications to the contrary, I should be more inclined to administer wine in large doses, and nutriment, than any particular drug. If the tendency to mortal asthenia can be staved off, the disturbance of the excito-motory apparatus may perchance subside or pass away.' The patient's sufferings may often be alleviated by the use of opium, or chloroform inhalation.

---

## XIX. TETANY

*Definition.*—By tetany is meant a peculiar affection characterised mainly by tonic, painful contractions of certain groups of muscles, primarily of the hands and forearms, but involving also not unfrequently the muscles of the lower extremities, and occasionally those of other parts of the body. The contractions are of variable duration, often intermittent, and bilateral.

*Causation.*—Tetany occurs mainly between the ages of fifteen or sixteen and thirty. It is by no means uncommon, however, in early childhood. In women it is particularly liable to come on during pregnancy and lactation; and in young children, as Dr. Abercrombie<sup>1</sup> shows, it has a clear association with rickets. Cold and damp, diarrhoea, and emotional excitement are severally recognised as important exciting causes. M. J. Simon records an outbreak of tetany in 1876 in a girls' school at Gentilly. Four or five and twenty cases occurred in the course of a month or five weeks. The first few were attributed to the influence of cold, the remainder to involuntary imitation.

*Symptoms and progress.*—The early symptoms of tetany are usually uncomfortable sensations or actual pain in the arms and forearms, and stiffness or contraction of one or more fingers, mainly induced by the attempt to use them. The disease develops rapidly. When at its height the thumbs are strongly adducted, while their terminal joints are extended; the palms of the hands are hollowed in consequence of the approximation of their borders; the fingers are slightly flexed at the metacarpo-phalangeal joints, but otherwise extended, and brought together in the form of a cone. Occasionally, the fingers instead of being pressed against one another are separated; and in rare instances the thumbs are adducted and the fingers flexed over them. Besides the affection of the fingers above described, the hands are generally somewhat flexed, and tilted towards the ulnar side; and in some cases the forearms are semi-flexed, the upper arms are adducted, and the hands thus become crossed upon the abdomen. When the lower extremities are involved, the toes are strongly flexed, the great toes occasionally being extended, while the feet are extended on the legs and the legs on the thighs. In severe cases the spasms may extend to the muscles of the back of the neck, to those of the trunk, to the diaphragm, and even to the muscles of expression, speech, and mastication. The affected muscles are rigid and painful, and resist passive extension, which also is attended with aggravation of pain. They resume their contracted form as soon as extension has been discontinued. The attacks of spasm are generally described as intermittent, lasting severally from a few minutes to half an hour or more at a time, seldom longer than twelve hours, and separated by intervals of variable duration, sometimes of a few days or even a few weeks. Not unfrequently, however,

<sup>1</sup> *On Tetany in Young Children.* A Thesis for the degree of M.D. in the University of Cambridge. 1880.

and certainly in children, the spasms, though presenting remissions, are continuous and last during the whole time of illness. Occasionally fibrillar tremblings of the affected muscles are observed. It is said by Trousseau that the spasms relax under the influence of chloroform. This, however, was not so in the cases described by Dr. Abercrombie. They continue (and this is a point of diagnostic importance) during sleep. Trousseau calls attention to the fact that during the intermissions of spasms these may be reinduced in the arms and sometimes in the legs by compression of the trunk arteries or nerves of the limbs. Another interesting phenomenon, which he terms 'facial irritability,' was observed in the tetany of children by Dr. Abercrombie. If the finger be drawn across the facial nerve, the orbicularis palpebrarum of the same side contracts, and in some cases there may also be contraction of the levator muscle of the corner of the mouth and of the ala of the nose. The phenomenon is often more marked on one side than the other.

Another remarkable feature of the disease is the occurrence of œdema, redness, and pain on the backs of the hands and feet. This does not appear to be by any means general; but at any rate, in a greater or less degree, it is a common incident of the disease in children. Rheumatic inflammation of joints is said to arise occasionally. In children again, as Dr. Abercrombie points out, laryngismus is very frequently associated with tetany.

Other symptoms attending tetany are by no means characteristic. Fever is seldom present. According to Erb there is increase of electric excitability in the peripheral nerves to both constant and induced currents, but not in the facial nerves—a point of some interest and obscurity taken in connection with Dr. Abercrombie's observation with regard to 'facial irritability.'

The course of tetany presents considerable variety. In some cases it lasts only a few days; much more frequently it continues for weeks or months. But in the last case its continuance is usually due to the occurrence of relapses. A few fatal cases have been recorded; mainly cases in which the affection was greatly prolonged, or in which symptoms pointing to implication of the medulla oblongata had supervened. The prognosis, however, on the whole, is decidedly favourable.

*Morbid anatomy and pathology.*—No distinctive or definite lesions have hitherto been discovered after death, to which the symptoms of tetany can be referred. Nothing in fact is known definitely in regard to the nature of the disease. That it does not depend on any coarse lesion of the central nervous system is certain. There is reason, however, to regard it as a so-called 'functional' disturbance of these parts (more particularly, no doubt, of the spinal cord), attended with increased irritability.

*Treatment.*—The most important point in the treatment of tetany is to attend to the patient's general health. Thus we have a hint as to treatment if the disease occurs in a rickety child, a woman who is suckling, a person who had been exposed to cold, a child in whom there is gastric irritation, or a girl who is hysterical or has experienced some

powerful emotional disturbance. In many cases tonics are indicated. Bromide of potassium, chloral, and opium have severally been strongly recommended. Cold and warm baths have been employed with trivial success. Electricity in its various forms has not hitherto been very efficacious. The constant current is to be preferred.

## XX. CONGESTION. ANÆMIA. SUNSTROKE

### A. *Congestion and Anæmia*

*Symptoms.*—So many nervous phenomena are commonly referred to congestion or anæmia of the nervous centres, that we can scarcely presume to pass these conditions over in silence. And indeed, although we are disposed to assert that the great majority of cases in which symptoms are referred to them in practice are not true examples of anything of the kind, it must be freely admitted that congestion and anæmia of the brain and cord do really play an important part in the phenomena of disease in these organs. Whenever inflammation or other processes of proliferation are in progress, congestion is necessarily present. We see the evidence of former congestion in the condition of the blood-vessels and of the parts immediately bounding them in chorea, epilepsy, tetanus, and chronic insanity. In heart-disease, in chronic bronchitis, in cases in which tumours press upon the large veins at the root of the neck, during violent muscular efforts, in the attacks of hooping-cough, the brain also becomes congested. Anæmia may be the consequence of abundant losses of blood; it may be due also to obstruction of the common or internal carotid, or of one of the arteries distributed to the brain. But in the majority of the above cases, either the symptoms which the patient presents are not those commonly attributed to congestion or anæmia, or the symptoms referrible to these conditions are intermingled and confused with others dependent upon causes of a different kind.

We shall not discuss the various symptoms, which on theoretical grounds might be attributed to cerebral and spinal congestion. It will be sufficient for our purpose to point out: that they must necessarily differ materially according as the congestion is acute or chronic, and according as it involves certain regions of these organs or pervades them generally; and that abnormal congestion, if it be not excessive, is likely to be attended with exaltation of function, if it be excessive is pretty certain to induce perversion or abeyance of function—vertigo, headache, delirium, convulsions, coma, paralysis, muscæ and dimness of sight, noises in the ears, and dulness of hearing. The effects of temporary congestion are sometimes well seen in attacks of spasmodic cough, such as attend pertussis, and the presence of thoracic aneurysms. The patient becomes livid in the face, suffers from vertigo, headache, muscæ, and noises in the ears, and presently becomes momentarily insensible, with probably some convulsive

twitchings or spasms of the muscles of the eyeballs and of those of expression.

The symptoms referrible to anæmia, equally with those due to congestion, vary according as the anæmia is general or partial, acute or chronic, slight or extreme. Moreover, they are very much of the same kind as those which attend congestion. Thus, in cases in which the supply of blood to the brain is suddenly interrupted either by obstruction of one or more of the arteries supplying it, or by temporary arrest of the heart's action, or by copious loss of blood, insensibility and convulsions frequently ensue; and again, upon anæmia more slowly produced, it is not uncommon for delirium resembling that of chronic alcoholism, or for acute mania, or for apoplectic symptoms to supervene.

In many of the cases in which cerebral anæmia or congestion has been diagnosed during life, the condition of the brain appears post mortem to have been perfectly healthy; and in some there has been found, from no obvious cause, accumulation of fluid in the ventricles or subarachnoid tissue. Hence it is possible that, at any rate in some cases, the symptoms referred to congestion or anæmia may really have been immediately due to the presence of serous effusion. It is possible, also, that in some cases they may have been due to the effects of undetected poisonous matters in the blood. Without venturing to decide upon what conditions of the brain each of them depends, we shall proceed very briefly to discuss two or three so-called functional disorders of this organ, which appear to belong to the group of affections we are now considering.

1. *Delirium tremens*.—We have already (page 623) fully described this affection as it occurs in drunkards; but it occurs also, though much less frequently, independently of alcoholism, and indeed in persons of abstemious habits, sometimes as a consequence of severe injury (*delirium traumaticum*), sometimes as a result of long-continued mental anxiety. The symptoms and progress of the disease are identical in all these cases, and need not again be detailed.

2. *Insanity*.—Various forms of insanity, especially perhaps mania, melancholia, and dementia, are apt to come on during convalescence from acute febrile diseases, and after profuse hemorrhages. Their symptoms are in no way distinguishable from those of the same forms of insanity occurring under other conditions. They generally, however, end in recovery.

3. *Eclampsia*.—The convulsive attacks which may attend these conditions vary from mere momentary spasms of the muscles of the eyeballs or face, or some other limited part of the body, attended with momentary loss of consciousness, to epileptiform seizures of the most violent kind. And, indeed, there is nothing in the attacks themselves by which they are distinguishable from those of true epilepsy. The differential diagnosis must rest upon the associated phenomena of the case, and upon its history and progress.

4. *Apoplexy and paralysis*.—The apoplectic attacks which appear to be due to merely functional disturbance of the brain have in many respects a close resemblance to those which are the result of hemorrhage. Their

onset is sometimes sudden ; but it is more commonly gradual, the patient becoming drowsy, then semi-comatose, and finally, perhaps after remissions, passing into a state of complete stupor. When the apoplectic condition is fully established, the patient is absolutely insensible ; his pupils are probably dilated and inactive to light ; he has lost the power of deglutition in a greater or less degree ; his breathing is probably explosive or stertorous ; his arms and legs are motionless and flaccid ; he has no control over his emunctories ; and his urine is retained. The phenomena may, however, be as varied as those due to sanguineous effusion ; and there are scarcely any of the symptoms which have been enumerated that may not fail in certain cases, or be replaced by some others. Especially it must be recollected : that partial or general convulsions may occur ; that the limbs, instead of being flaccid, may be rigid ; and, indeed, that there may be distinct hemiplegia. The main distinctions between functional apoplexy and that from effusion of blood reside in their usually different modes of onset ; in the paralysis, which in functional apoplexy is mostly general and attended with flaccidity ; in the pulse, which is usually accelerated in the affection now under consideration ; and in the temperature, which here generally rises from the commencement of the attack, whereas in cerebral hemorrhage, for some hours at least, it usually falls.

These comatose attacks are not limited to elderly persons ; they are consequences of lateral and disseminated sclerosis, and especially of general paralysis of the insane ; and affections not clearly distinguishable from them are occasionally observed in young children, in whom they simulate the phenomena of meningitis.

In connection with the apoplectic attacks, and occasionally independently of them, hemiplegic and other paralyzes may occur. Affections of the sensory nerves also may supervene ; and the patient may have dimness or loss of vision, or analagous conditions involving the sense of hearing.

It need scarcely, perhaps, be said : that in each of the above cases the progress of the affection may closely simulate that of the malady which in its symptomatic phenomena it most closely resembles ; that in many instances complete recovery takes place within a shorter or longer time ; that in some instances relapses occur after such recovery ; that in some permanent mental defect or paralysis follows ; and that not unfrequently death ensues.

*Treatment.*—It is impossible to lay down any definite rules for the treatment of these various functional disturbances. In the majority of cases the treatment should no doubt be the same as that for the affections which they resemble. It is important, however, to bear in mind that if they be traceable in any degree to loss of blood, to want of food, or to anæmia, however produced, it becomes essential to support the patient's strength by food and tonics.

B. *Sunstroke.* (*Coup de Soleil.* *Calenture.* *Insolatio*)

*Definition.*—By the term ‘sunstroke’ is usually implied a more or less sudden attack of unconsciousness, occurring in persons exposed, under adverse conditions, to high temperature. It seems probable, however, that more than one affection is included under this name.

*Causa ion.*—Sunstroke appears to result from prolonged exposure to intense heat, especially if the atmosphere be at the same time damp and impure, and the patient exhausted by long-continued over-exertion, and the wearing of clothes and accoutrements which impede the free action of his respiratory muscles. It often occurs, especially in tropical climates, from exposure to the direct rays of the sun; but it is common also even in the night-time among persons who are subjected to intense heat in close, over-crowded, and ill-ventilated barracks, houses, or ships. Soldiers engaged in long and toilsome marches under the glare of a tropical sun are especially liable to suffer.

*Symptoms and progress.*—Sunstroke is sometimes sudden in its onset, but is more frequently preceded by premonitory symptoms. In the former case, the patient, who is probably engaged in some laborious occupation and exposed to the sun, suddenly falls down insensible and collapsed, with pale, cold, moist skin, gasping respiration and extreme feebleness and rapidity of pulse. There is no doubt that, in these cases, equally with those next to be considered, the internal temperature at the time of the attack is above the normal. Death under these circumstances not unfrequently takes place with great rapidity, or even quite suddenly.

The premonitory or early symptoms of the other variety of the affection comprise, in a large proportion of cases, great sense of weariness and prostration, vertigo, nausea, dryness and heat of skin, tendency to frequent micturition or even incontinence of urine, and restlessness or sleeplessness. The actual attack is sometimes ushered in with drowsiness, and the patient lays himself down to rest or sleep; in other cases he is seized with momentary delirium or mania, more rarely with convulsions. Under any circumstances the patient rapidly becomes comatose or apoplectic, and then presents most of the ordinary phenomena of this condition. He lies perfectly insensible; his pupils are contracted and unaffected by light, his conjunctivæ injected; he breathes rapidly, noisily, and sometimes stertorously; his pulse is frequent, small, weak and often irregular; his face is pallid; and his skin intensely hot. In some instances the patient remains quiet during his comatose condition; in others he is attacked with local or general convulsions. If death takes place it is rarely delayed beyond twenty-four or forty-eight hours.

The mortality from sunstroke is very heavy, exceeding 40 per cent. Recovery is sometimes sudden and complete; but it is more commonly slow, and attended for some few days by feebleness of the heart’s action and oppressed breathing, and is then not unfrequently followed by consequences of more or less importance, such as headache, chorea-like affections of the

muscles, epilepsy, and some degree of mental imbecility. These sequelæ may be permanent.

*Morbid anatomy and pathology.*—In most cases of fatal sunstroke the blood is found to have remained uncoagulated ; the lungs are intensely congested, and the right side of the heart is loaded with blood ; further, there is generally engorgement of the vessels of the brain. The proximate cause of the disease is uncertain. By some it is considered that the symptoms are due to the circulation of poisonous matters in the blood. It is suggested by Dr. G. Johnson that the intense heat of the body is attended with dilatation of the pulmonary capillaries, engorgement of the lungs, and asphyxia, upon which the other phenomena of the disease presently supervene. The first symptoms, however, in many cases, are those of unconsciousness, and in all coma rapidly comes on with involvement of those organs, especially, which are in relation with the pneumogastric nerves. The symptoms differ indeed little, if at all, from those of the typical apoplectic state ; and it is difficult therefore to believe that they are not primarily cerebral.

*Treatment.*—Indian practitioners are unanimous as to the danger of bleeding in these cases, and are equally unanimous with respect to the value of the cold douche, or of cold applied in other forms, as by means of the cold pack or cold bath ; measures which are of the greatest efficacy in all forms of hyperpyrexia. Especially it seems advisable to apply cold to the head. Subsequently, if consciousness do not return, the head may be shaven, and counter-irritants used. The bowels should be made to act, but not violently purged. Generally, also, it is better to give nourishment and diffusible stimulants than to deplete.

---

## XXI. MEGRIM. (*Migraine. Hemicrania. Sick-headache*)

*Definition.*—A form of headache, for the most part circumscribed, coming on in paroxysms, and frequently attended with sickness, affection of sight, and other nervous phenomena.

*Causation.*—Megrim appears in a large number of cases to be an hereditary disease ; and, when of distinctly hereditary origin, not unfrequently commences during the period of the second dentition, from which age up to thirty it usually first declares itself. It rarely commences after thirty, and generally, even in those who are liable to it, subsides with advance of years. Patients do not often suffer from it after fifty. Females are somewhat more prone to it than males. The determining causes of the attack are very various. Amongst the most common of them are, disturbance of the digestive organs, such as may arise from over-feeding or prolonged abstinence, uterine disorders and the catamenial period, sustained mental labour or excitement, emotional disturbance, bodily fatigue or want of exercise, insufficient or over-abundant sleep, overcrowded rooms, foul air, and meteorological conditions ; and, besides these, impressions

upon the senses, such as are produced by glaring lights, rapid successions of objects presented to the eye, loud or discordant noises, strong odours, and offensive smells. Megrim, or a condition undistinguishable from it, may arise also in the course of an ordinary catarrh, or be induced by exposure of the head to a current of cold air, or by malaria.

*Symptoms and progress.*—In the simplest and most common form of megrim, the patient is attacked, more or less suddenly, with dull pain, usually referred to a limited surface immediately over the eye or in the temple. This gradually extends in area, and becomes more intense, but usually still remains limited to one side of the head. It varies in intensity from time to time, is for the most part aching, but is not unfrequently attended with sudden shootings, and generally with throbbing, which is always greatly increased by bodily or mental exertion. It often involves the eye; and this, together with the scalp, is apt to become hyperæsthetic or tender. The head generally is hot, and the arteries of the affected region manifestly dilated. In many cases the pain affects both sides of the head, although even then it is usually more intense on one side than the other; occasionally it attacks the occipital instead of the frontal region; and sometimes it becomes generally diffused. From the commencement the patient is dull and indisposed for or incapable of mental or bodily exertion, and with the continuance of the headache these conditions increase upon him, and he becomes pale and chilly, and looks heavy, dejected, and miserable. Not unfrequently he has a vague dread, or sense of impending evil; and especially he is apt to experience a general feeling of profound illness, attended with tremulousness, shivering, and weakness of the limbs. The pulse for the most part is small and weak, and often slower than natural. After a variable time a sense of nausea supervenes, and in a large proportion of cases culminates in vomiting, during the attacks of which the headache generally attains its greatest degree of intensity. After the vomiting has ceased the patient probably goes to sleep, and at the end of some hours awakes in pretty nearly his usual health.

In a large number of cases other symptoms are associated with those just considered, and then for the most part precede them. Among the most interesting of them are disorders of vision. When these occur, they are probably always the earliest in the sequence of events; and they generally vanish with the supervention of headache. They vary in character: in some cases certain portions of the retina become simply insensible, and if the central spots of the eyes be involved, the patient, who probably feels well in all other respects, notices that he cannot see the nib of the pen with which he is writing, or the letters which he is forming, or that, while distinguishing all other parts of the body, he cannot see the face of the person at whom he is looking; in some cases he observes a tremulous, vibratile or rotatory movement in some part or other of the field of vision; sometimes these tremulous areas or spectra become variously coloured; double vision sometimes occurs. The patches of retinal anæsthesia, or derangement, appear always to occupy identical

parts in both eyes, and are apt to vary in shape from time to time. The colouration of the spectra, when it occurs, is always secondary.

Other senses are apt to suffer, but on the whole much less frequently than sight; and the phenomena referrible to them, when associated with ocular derangements, always come on later. Occasionally the patient experiences deafness or noises in the ears, or loss or perversion of taste or smell; but more frequently, perhaps, he is attacked with numbness, passing on, may be, to complete anæsthesia of the upper extremity of the half of the head and neck and face, and even of the parts within the mouth, all on the same side as the cephalic pain. This loss of sensation is sometimes associated with muscular paralysis. Further, the cephalalgia is not unfrequently associated with the presence of distinct neuralgic pains, not only at the back of the head, but in the back and side of the neck, and even in the shoulder and down the arm.

It has already been observed that the patient becomes dull and apathetic and incapable of intellectual exertion; but psychological phenomena of a more remarkable kind are apt to ensue. Sometimes there is marked mental confusion or incoherence of thought, sometimes indeed typical aphasia. Drowsiness is very common: often forming one of the earliest indications of the attack; sometimes coming on during its progress, and culminating in a more or less prolonged semi-comatose condition; but much more frequently constituting the termination of the attack.

Megrim begins in many different ways. In some cases it supervenes immediately upon exposure to its exciting cause, as when the characteristic headache attacks the sufferer while he is at the theatre, or at a picture gallery, or during exposure to discordant noises or offensive smells, or while he is engaged in some laborious mental occupation. Not unfrequently it comes on during the night, the patient waking from time to time with the consciousness of heaviness in the head, and getting up with the attack well developed; or it manifests itself when he wakes in the morning, or immediately after rising. In other instances it comes on at various times of the day, without obvious immediate cause. In a large proportion of cases the headache is the first symptom. In many, however, this is preceded by some of the prodromal phenomena above considered: the patient experiences a sense of general illness or of depression or dread; or he has numbness, or confusion of thought, or extreme drowsiness, or other of the physical phenomena which have been enumerated; or he has some affection of vision. It is curious, as we have already shown, that when these several phenomena, or any of them, manifest themselves, they almost invariably precede the headache. The attack may be limited to any one of these symptoms.

The duration of megrim varies for the most part between twelve and twenty-four hours; it may, however, last an hour or two only; and it may be prolonged, but generally by successive relapses, for several days. The subsidence of the attack is generally gradual; in a large number of cases, it is preceded by vomiting; and in the great majority (whether vomiting

have taken place or not) the patient after a while sinks into a profound sleep, from which he wakes refreshed, and probably well. During convalescence he often perspires profusely, and excretes a large quantity of urine.

Megrim is essentially a periodical disease, and in those who are liable to it not unfrequently comes on with more or less regularity once a week, once a fortnight, or once a month. It not uncommonly, however, occurs less regularly, and more distinctly in response to certain definite causes to which the patient exposes himself. Moreover, it often ceases for a time under various circumstances, such as pregnancy, suckling, and change of air or occupation, and occasionally is developed only at long intervals in connection with special causes of ill-health.

*Pathology.*—Megrim has often been regarded as essentially a symptom of disorder of the liver or stomach; and no doubt affections of these viscera, but more particularly of the stomach, must be regarded as some of its exciting causes. But, on the other hand, the attacks so frequently arise independently of any morbid state of the digestive organs that we are compelled to look elsewhere for its essential seat. It has latterly been referred to disorder of the cerebral circulation due to the influence of the vaso-motor nerves on the vessels of the part supposed to be implicated. Dr. Latham believes that its primary cause is some affection of the vaso-motor nerves, in virtue of which the vessels become contracted and the tissues anæmic; and that it is to anæmia thus produced of the central nervous organs that the defects of vision and other early phenomena are due. And he refers the headache, which is generally if not always attended with manifest dilatation and throbbing of the temporal arteries, to secondary hyperæmia. Dr. Liveing, however, points out that even if, as seems not improbable, some of the phenomena are referrible to anæmia and hyperæmia, there must still be some antecedent cause to which the vaso-motor affection itself is due. And he contends that the phenomena of the disease depend on the irregular accumulation and discharge of nerve-force; that the immediate antecedent of the attack is a condition of unstable equilibrium, and gradually accumulating tension in the parts of the nervous system more particularly concerned; and that the paroxysm itself may be likened to a storm. He regards the optic thalami and all those parts which lie between these bodies and the roots of the vagi as the seat of disease. Megrim would seem, according to this hypothesis, to have a close pathological relation with epilepsy. The diseases do not, however, pass into one another.

*Treatment.*—In the first place it is important for the patient to avoid those conditions to which his attacks seem to be traceable; it is especially important also for him to live wholesomely, to avoid gastro-intestinal disturbance, to take plenty of exercise, to inhale the fresh healthy air of the country, and to refrain from too prolonged or intense mental labour, worry, or excitement. Various remedies are employed, reputedly with success, to prevent the occurrence of attacks of megrim: among others, iron, zinc, arsenic, iodide, bromide and chloride of potassium, quinine, strychnia, belladonna, hyoscyamus, cannabis indica, and valerian. During

the paroxysms nothing is so efficacious as complete rest in the recumbent posture, in a darkened and perfectly quiet room. Relief may often be afforded, however, by the administration of strong tea or coffee, or of caffeine, theine, guarana, or croton chloral. A full dose of salicylate of soda combined with a few grains of citrate of caffeine, to be repeated if necessary, has been strongly recommended by Dr. Jas. Little, and certainly often gives relief. Another valuable remedy is antipyrin in doses of 15 or 20 grains. Opium or morphia, in sufficient quantities to ensure sleep, and especially given by subcutaneous injection, is often of the greatest value in the treatment of the attack. Occasionally a full dose of brandy, ammonia, or one of the fixed alkalies benefits the patient. An evaporating lotion, belladonna, or aconite locally applied is often of great service. The aconitia ointment is especially valuable in many cases in warding off or subduing the headache. Hot applications sometimes afford relief; as also do counter-irritants applied either directly to the painful part or to the back of the neck. But local measures, although they relieve pain, seldom prevent or curtail the other phenomena of the attack. The headache may sometimes also be soothed by pressure upon the carotid or temporal artery of the affected side.

---

## XXII. MÉNIÈRE'S DISEASE (*Aural Vertigo*)

*Definition.*—A disease characterised by sudden attacks of vertigo in connection with lesions of the semicircular canals.

*Causation and pathology.*—Experiments performed on the lower animals, in the first instance by Flourens and subsequently by other observers, have distinctly proved that injury of the semicircular canals is followed by vertiginous movements, which have some definite relation to the particular canal operated upon. To this subject attention has already been directed. It was M. Ménière, however, who first, in the year 1861, recognised and described the phenomena due to disease of these organs in the human being.

Many cases have now been recorded in which the group of symptoms presently to be considered has been found associated with impairment of hearing; and in several of them post-mortem examination has revealed the presence of inflammatory exudation strictly limited to the semicircular canals. There is good reason, however, to believe that similar effects may be produced indirectly in diseases of the middle ear or other neighbouring parts, by the pressure which is apt to be exerted upon the contents of the labyrinth, and through them on the semicircular canals. Hence they may result from catarrh, and complicate ordinary forms of otitis.

*Symptoms and progress.*—The specific phenomena of Ménière's disease are sometimes preceded by deafness, ear-ache, and other indications of aural mischief. But in a considerable number of cases they manifest themselves without any such prodromata. The patient is suddenly

attacked with noises in his ears, or in one of his ears, and a feeling of vertigo—symptoms which are attended with faintness, pallor, perspiration, nausea, and probably actual vomiting. The attack is of short duration, sometimes lasting two or three seconds only ; and usually the recovery of the patient from it is for a time complete.

The noise, as above stated, is sometimes referred to one ear only, sometimes to both ; but in the latter case it is generally more pronounced on one side than the other. It differs in intensity in different cases, and is variously described as buzzing, humming, whistling, or singing, and is likened sometimes to the puffing of a steam-engine, sometimes to a sudden explosion. The sense of vertigo varies in severity and duration ; in some cases there is a mere momentary feeling of giddiness, or a feebler but more prolonged sensation of swimming in the head which resembles that attending sea-sickness ; in some cases the patient feels as if he were suddenly thrown forwards, backwards, or laterally, or rotated, and he staggers or falls in the direction which corresponds with his sensation, clutching at neighbouring objects for support, or actually falling to the ground. The attack is always attended with a sense of anxiety or alarm and faintness. The latter condition may reveal itself by momentary pallor, præcordial anxiety, and failure of cardiac action, or by all the ordinary signs of well-marked syncope, followed by sweating, and extreme rapidity and feebleness of pulse. A feeling of nausea is probably always present in a greater or less degree ; but not unfrequently vomiting ensues, and with its occurrence the attack usually comes to a close.

The vertiginous seizure, however severe it may be, is never attended with actual loss of consciousness ; and there is never any convulsive movement, paralysis, implication of speech, squinting, sensation which can be likened to the epileptic aura, or indeed any phenomena, beyond those above described as constituting the attack, which in any sense point to the presence of cerebral mischief. Headache even is unfrequent.

The fits come on in the first instance at irregular and probably distant intervals ; but they tend gradually to increase in frequency and to approach one another ; and sooner or later, probably, a time arrives when the patient, though still suffering from frequent paroxysms, is never free from some degree of vertigo.

The noises in the ear which attend the early attacks of vertigo are not necessarily associated with deafness ; indeed, sometimes hearing is preternaturally acute, and discordant or loud noises are peculiarly painful to the patient. Occasionally the range of audition becomes contracted. At this time also it not unfrequently happens that no affection of hearing is observable between the attacks. But by degrees the noises in the ear become constant, though still undergoing exacerbation when the paroxysms occur ; and the sense of hearing grows gradually more obtuse, until ultimately absolute deafness of the affected ear probably ensues. It is curious that, with the supervention of absolute deafness, not only do the paroxysmal attacks generally cease, but with them the continuous sense of giddiness which had probably also been present.

Slight and momentary attacks of giddiness, essentially resembling those above described, are by no means uncommon in connection with various temporary or permanent affections of the middle ear, and are then frequently induced immediately by loud or discordant noises, or by other powerful impressions on the senses. In such cases, however, complete recovery may be anticipated, and the disease seldom takes the course above sketched.

*Treatment.*—It is impossible to lay down rules for the treatment of Ménière's disease. It is important, however, to bear in mind that the vertiginous attacks are relieved, though not prevented, by lying down, and in many cases by carefully protecting the patient from all noises and other such influences. Further, it is obvious that when the symptoms depend on the presence of disease in the accessible parts of the ear treatment directed to these parts should be employed. Quinine seems often useful.

### XXIII. LOCAL PARALYSES.

#### A. *Paralysis of the Third, Fourth, and Sixth, or Oculo-motor Nerves.*

*Causation.*—Paralysis of these nerves is probably always the consequence of some lesion involving them either at their origin or in some part of their course. Among such lesions may be named syphilitic disease of the base of the skull or contiguous parts of the brain; tubercle, carcinoma, or other forms of morbid growth, or inflammatory exudation, occupying the same situations; tumours or accumulations of fluid or blood situated in the superincumbent brain-substance, and causing pressure; and aneurysms or tumours in the course of the cavernous sinuses. Oculo-motor palsy is common in locomotor ataxy, and is the essence of ophthalmoplegia externa.

*Symptoms and diagnosis.*—In order to determine the situation of lesions causing the various oculo-motor paralyses, and to distinguish the paralyses due to individual nerves, it is essential, on the one hand, to have a clear view of the relations of the oculo-motor nerves at their origin and in the various parts of their course; and, on the other hand, to have an exact knowledge of the normal actions of the muscles which they supply.

In reference to the anatomical point, it must be borne in mind: that the nuclei of the third and fourth nerves are in close relation with one another in the floor of the iter, and that the sixth arises in common with the facial, in the floor of the fourth ventricle; that the muscles supplied by these nerves are seven in number, namely, the levator palpebræ superioris, the four recti, and the two obliqui; and that of these the external rectus is supplied by the sixth alone, the superior oblique by the fourth alone, and all the other muscles by branches of the third.

The muscles of the eyeball are six in number, and arranged in antagonistic pairs, which severally rotate the eyeball in opposite directions upon

an axis perpendicular to the plane in which they respectively act and passing as nearly as possible through the central point of the globe of the eye. These several pairs are the internal and external recti, the superior and inferior recti, and the superior and inferior obliqui. And the axes of rotation of the eyeball which correspond to them (see fig. 107) are (supposing the left eye to be under consideration, and its line of vision to be fixed directly forwards):—for the external and internal recti, a vertical straight line passing through the centre of the eye; for the superior and inferior recti, a horizontal straight line ( $rr$ ) passing obliquely through the centre so that its nasal extremity is a little in advance of its temporal extremity, and forming an angle of about  $70^\circ$  with the line of vision; for the obliqui, another horizontal straight line ( $oo$ ) passing also obliquely through the centre, but in such a direction that it makes an angle of  $35^\circ$  only with the line of vision—its temporal extremity being just a little beyond the outer margin of the cornea, and its nasal extremity towards the back of the eye, a little internal to the optic disc.

FIG. 107.—Horizontal section of left eye seen from above.

$a$ , Antero-posterior diameter of eye;  $b$ , transverse diameter of eye;  $rr$ , fixed axis of rotation for movements effected by superior and inferior recti;  $oo$ , fixed axis of rotation for movements effected by obliqui.

It may be assumed as sufficiently accurate for all practical purposes: that the ball of the eye is globular; that it is lodged in a socket bounded by fat, connective tissue, and membrane, in which it moves as the head of the femur moves in the cotyloid cavity; that its centre of rotation is the actual centre of the eye; and further, as Helmholtz shows, that in consequence of the fixed origins of the oculo-motor muscles, and their broad insertions, the three axes of rotation which have been indicated remain unalterable in their relation to the fixed points of the orbit, no matter how much the line of vision—the line in which the eye is looking—becomes altered.

It follows (see fig. 108) from the above considerations: first, that the internal and external recti always cause the cornea to revolve around a vertical axis, to move therefore either in a horizontal equatorial line or, in proportion as it is elevated or depressed below this line, in the arcs of smaller and smaller parallel circles; second, that the superior and inferior recti always cause the cornea to revolve around the oblique horizontal axis, whose position has already been defined, and hence in the arcs of circles which are parallel to a vertical equatorial section of the eyeball, made through or near the outer margin of the cornea (as the eye looks directly forwards) in front, and the inner margin of the optic disc behind, so that the circles to which these arcs belong become smaller and smaller from the outer to the inner canthus of the eye, and the influence of the recti in causing vertical movements of the cornea

correspondingly diminished; third, that the obliqui always cause the cornea to revolve around the oblique horizontal axis which has been referred to these muscles, and hence in the arcs of circles which are parallel to a vertical equatorial section of the eyeball, made through or near the inner canthus;

FIG. 108.—Left eyeball with iris and pupil seen from the front.

*o*, Anterior pole of axis of rotation for obliqui; *r*, anterior pole of axis of rotation for superior and inferior recti; *b b*, upper and lower poles of axis of rotation for internal and external recti.

The concentric circles round *o* and *r* respectively indicate the direction and amount of movement of the different parts of the globe due to the action of the obliqui and superior and inferior recti respectively; the horizontal lines have a similar relation to the movements about the axis *b b*.

the object, as seen by the squinting eye in relation to that seen by the normal eye, being either internal or external to it, above or below it, or tilted. The existence of double vision is sometimes not recognised by the patient when the axes of his eyes diverge very widely; moreover, the double image tends to merge into one, and the squint to become unapparent, as the patient turns his sound eye in the direction towards which the squinting eye inclines.

In testing the eyes with the object of discovering the existence of double vision and the peculiarities it may present, it is generally convenient to place a coloured glass before one of them, in order that the patient may be able to distinguish and indicate by their respective colours the two images which he sees.

Assuming the left eye to be affected, the following would seem to be the consequence of paralysis of its several muscles taken singly:—

*Internal rectus*.—Outward squint. Displacement of false image in horizontal line, to patient's right. Image not tilted. (See fig. 109.)

*External rectus*.—Inward squint. Displacement of false image in horizontal line, to patient's left. Image not tilted. (See fig. 110.)

*Superior rectus*.—Downward squint. Displacement of false image upwards. Elevation of pupil above horizontal line effected solely by inferior oblique; its upward movement, therefore, is in a curve directed upwards and to the left; it is ample when the pupil is directed inwards,

that, while all horizontal consensual movements of the two eyes can be effected by means of the inner and outer recti only, all vertical consensual movements require the co-operation of the superior and inferior recti and obliqui.

Paralytic affections of the muscles of the eyeball are attended for the most part with squinting and double vision—the direction and character of the squint being different for each muscle affected, and the position of

but, when the pupil is directed outwards, consists in a mere rotation of it upon its axis. Under these circumstances, the false image is tilted to the patient's right. (See fig. 111.)

*Inferior oblique.*—Downward squint. Displacement of false image upwards. Elevation of pupil above horizontal line effected by superior rectus; its upward movement, therefore, is in a curve, directed upwards and to the right; it is most ample when the pupil is directed outwards. The false image, when the pupil is above the horizontal line, is tilted to the patient's left. (See fig. 112.)

*Inferior rectus.*—Upward squint. Displacement of false image downwards. Depression of pupil below horizontal line accomplished by superior oblique. Its downward movement consequently is in a curved line, directed downwards and to the left, being a mere revolution upon its axis when the eye is directed outwards, but becoming more and more ample as the eye turns to the right. False image, when patient is looking downwards, tilted to his left. (See fig. 113.)

*Superior oblique.*—Upward squint. Displacement of false image downwards. Depression of pupil below horizontal line effected by inferior rectus. Its downward movement takes place, therefore, in a curved line directed downwards and to the right, the movement being most ample when the eye is directed outwards, least ample when it looks inwards. When the pupil is below the horizontal line, the false image is tilted to the patient's right. (See fig. 114.)

It does not generally happen, however, that one muscle only is affected, unless it be the external rectus, or that when two or three muscles are involved they are completely paralysed; and consequently it is often difficult to determine the respective shares which different muscles take in oculo-motor paralysis. Paralysis of the third pair very frequently causes ptosis, together with dilatation and immobility of the pupil. When the oculo-motor branches of the third nerve are all implicated, the eye assumes an external squint, and the pupil is commonly directed a little downwards. Paralysis of the sixth pair is not unfrequently bilateral, probably because, from the long

FIG. 109.

FIG. 113.

FIG. 114.

In the above diagrams the thick cross represents the true image, the thin cross the false image.

course which these nerves take along the floor of the skull, and from their position between this and the pons, they are peculiarly exposed to pressure and involvement in intra-cranial inflammatory and other morbid processes.

*Treatment.*—The treatment of paralysis of the muscles of the eye must be determined by the opinion we form of the nature of the lesion causing it. Iodide of potassium and mercury are indicated in syphilitic cases. Electricity, applied to the muscles, is sometimes serviceable. However it may be explained, patients often recover from these paralyses.

### B. *Paralysis of the Fifth Nerve.*

*Causation.*—This, like paralysis of the oculo-motor nerves, may be caused by various lesions implicating the nucleus of the nerve or the nerve itself in some part of its course. It is most commonly of syphilitic origin.

*Symptoms and diagnosis.*—The nerve may be implicated wholly or in part, and in the latter case the affection may be limited either to its ophthalmic, to its superior maxillary, or to its inferior maxillary division. When the affection is total, there is complete anæsthesia of all those parts to which the nerve is distributed, and at the same time complete paralysis of all the muscles of mastication which it supplies. The loss of sensation involves the anterior half of one side of the head and face as far back as the ear, inclusive of the conjunctiva, cornea, and eyelids, the mucous membrane of the nose, lips, cheek, gums, and palate, the tongue (excepting in the neighbourhood of the circumvallate papillæ), and the external auditory meatus. Consequently the conjunctiva is insensible to all external impressions, and liable, therefore, to get irritated and inflamed—its irritation, moreover, is unattended with reflex phenomena; the sense of smell is impaired, mainly from tendency of the Schneiderian membrane to inflame, but partly from loss of power to appreciate impressions made by pungent vapours or gases; the sense of taste is annulled in the anterior two-thirds of the tongue; and, partly from the loss of ordinary sensation in one half of the oral mucous membrane, mastication becomes difficult on the corresponding side, and food tends to collect, unknown to the patient, between the cheek and gums, or between these and the tongue.

The chief muscles supplied by the motor portion of the nerve are the temporal, masseter, and pterygoids. The temporal closes the jaw, and at the same time draws it backwards; the masseter and internal pterygoid also close the jaw, but tend to draw it forwards; the external pterygoid co-operates to some extent with the last, but is especially the muscle by which the jaw is thrown forwards. Collectively they close the jaw, and effect the various horizontal movements of trituration. If they be paralysed, neither the temporal nor the masseter can be felt to harden in contraction as does that of the healthy side, when the teeth are being firmly closed; when the lower jaw is retracted it is drawn back obliquely with an inclination to the healthy side; when it is protruded, it is protruded obliquely with an inclination to the paralysed side. The last

deformity becomes especially remarkable when the patient opens his mouth wide, for not only is the jaw then displaced in a very high degree towards the paralysed side, but the oral orifice becomes lopsided, and the muscles connected with the affected side of the lower lip appear to act more powerfully than their fellows. The difficulty of masticating on the diseased side is necessarily largely dependent on the weakness of its muscles.

We have referred to the tendency which the affected side has to get congested and inflamed. These conditions may supervene in the mucous membrane of the mouth or nose, or in the conjunctiva. It is most commonly observed, however, in the cornea, which is apt within a few days of the occurrence of paralysis to become opaque, to ulcerate, and to slough. These nutritive lesions doubtless obey the law which has previously been considered; that is, they occur not so much when the continuity of the nerve is absolutely destroyed as when the implication of the nerve or of its nucleus is incomplete and irritative. Under the same circumstances, loss of faradic contractility of the paralysed muscles and wasting are likely to come on quickly.

If the affection of the fifth nerve involve only one of its main branches, the paralytic symptoms will of course be limited to the distribution of that branch. Accordingly, if the ophthalmic division be alone affected, the anæsthesia will occupy the front of the forehead, the upper eyelid, the conjunctiva, and a part of the mucous membrane and integument of the front of the nose; if the superior maxillary branch, the anæsthesia will involve the cheek, the lower eyelid, and upper lip, together with the side of the nose, a portion of the temple, the interior of the nose, and the mucous membrane of the cheek, upper gums, and palate; if the inferior maxillary, the lateral part of the head and face, with the ear, the lower lip and gums, the tongue, and the muscles of mastication; if the motor portion, the muscles of mastication only.

*Treatment.*—If the disease be syphilitic, antisyphilitic remedies are indicated; but in other varieties of organic disease medicinal treatment can have but little influence. If the affection be hysterical, or due to inflammation or other removable causes, faradism or galvanism may be serviceable in hastening the restoration both of sensation and of voluntary movement.

### *C. Paralysis of the Portio Dura (Bell's Paralysis)*

*Causation.*—This may be caused by any lesion implicating the nucleus of the seventh nerve in the floor of the fourth ventricle, or involving the nerve in any part of its course thence: either as it passes through the substance of the pons, or between its apparent origin and the internal auditory meatus, or in its passage along the aqueduct of Fallopius, or after its emergence from the petrous bone. It may be caused: within the skull, by either extravasation of blood, inflammatory mischief, or syphilitic or other growths; in its passage through the bone, either by fracture, or by morbid growths originating in the bone-substance, or in

connection with caries of the internal or middle ear, or in consequence of inflammation attacking the nerve itself. Externally to the petrous bone, it may be due to injury, as sometimes happens to the infant during delivery by the forceps, or to inflammatory or other lesions of the parotid or other tissues in the vicinity. The most common and interesting cause of Bell's paralysis is inflammation of the nerve, often within the aqueductus Fallopii—a condition which is readily induced by allowing a draught of cold air to play on the side of the face. Hence not uncommonly it is traceable to a railway journey in which the patient has been sitting facing the engine and next an open window, or results from exposure, while sleeping, of one side of the face to a current of air.

*Symptoms and diagnosis.*—Inflammatory, or so-called 'rheumatic,' paralysis is generally of rapid development, and is not necessarily attended with pain or constitutional disturbance. Yet not unfrequently the draught which causes the paralysis causes also earache, or neuralgic phenomena referrible to the fifth nerve. The symptoms of Bell's palsy are very striking: all the muscles supplied by the seventh of one side are paralysed; the half of the face, consequently, is without motion and expressionless; the wrinkles are smoothed away, and the predominant action of the opposite muscles draws the mouth over to that side. When the patient wrinkles his forehead in surprise, the healthy half becomes, through the agency of the occipito-frontalis, transversely furrowed; when he frowns, the corrugator supercili contracts the same part into vertical folds; but in both cases the forehead on the affected side remains perfectly smooth. The orbicularis palpebrarum ceases to act, so that the eye remains open, and the conjunctiva, from the loss of its habitual protection, becomes watery and inflamed. M. Duchenne points out that this condition is sometimes associated with epiphora, and he attributes this circumstance to the fact that the tensor tarsi is then paralysed as well as the orbicularis itself, and consequently fails to retain the puncta in the position best adapted for carrying off the lacrymal secretion. The ala of the nose gets flaccid, and the corresponding nostril loses its rotundity. The cheek is motionless, and smooth and limp; the natural furrow beneath the eye and that descending from the side of the nose become indistinct; and when the patient coughs, or blows through his mouth, the cheek, owing to paralysis of the buccinator, undergoes momentary distension. The mouth is drawn to the opposite side; when it is shut, the paralysed half closes less perfectly than the other; when it is opened, that half opens less completely; and the more powerfully he exercises his facial muscles, as in laughing and crying, the more extreme does its lateral distortion become. He has lost the power of whistling, and probably that of blowing out a candle; his utterance is somewhat impaired; he has difficulty in retaining fluids in his mouth, especially in the act of drinking; and food tends to collect between the teeth and the paralysed buccinator. There is no anæsthesia.

There are some important distinctions between paralysis due to direct implication of the portio dura and paralysis of the same nerve of hemi-

plegic origin. In the first place, in hemiplegia the paralysis rarely involves materially those branches of the portio dura which are distributed to the eyelids and upper half of the face, while in primary affection of the nerve the paralysis is general. In the second place, in hemiplegia not only is there more or less general unilateral palsy, but the motor branch of the fifth pair and the hypoglossal are involved together with the facial; while, in the other case, the temporal, masseter, and pterygoid muscles still act perfectly, and the movements of the tongue are in no degree compromised. Lastly, in hemiplegia the facial paralysis is rarely absolute even in the parts chiefly affected, and the paralysed muscles retain their bulk and faradic contractility, while in Bell's paralysis the loss of power is usually absolute, and the muscles lose their electrical contractility very rapidly, sometimes in less than a week. In neither case are the muscles of the eyeball and the levator palpebræ implicated.

The phenomena above enumerated are those which most commonly attend Bell's paralysis, and are the only ones which attend it when the lesion causing it is situated below the junction of the portio dura with the Vidian nerve; but other phenomena are apt to be superadded in proportion as the disease causing paralysis approaches nearer and nearer to the origin of the nerve. If the disease be so situated as to involve the chorda tympani and petrosal nerves, the patient is likely to suffer: first, from over-acuteness or painfulness of hearing, which has been attributed to relaxation of the membrana tympani from paralysis of the tensor, but is by Brown-Séquard believed to be due to hyperæsthesia of the auditory nerve dependent on involvement of the sympathetic branch supplying its blood-vessels; and second, from dryness of the half of the tongue corresponding to the paralysed half of the face, and some impairment of taste, owing to implication of the chorda tympani and consequent interference with the salivary secretion, and to some obscure influence exerted directly on the tongue. Unilateral paralysis of the soft palate has been supposed to be due to affection of the portio dura. It appears certain, however, that it depends on affection of the spinal accessory, and that consequently it is apt to be associated with laryngeal paralysis of the same side. This paralysis is revealed partly by the fact that, from involvement of the corresponding half of the azygos uvulæ, the uvula when at rest, and still more when in motion, is so curved that its point is directed away from the paralysed side; and partly by the condition of the corresponding arch of the fauces, which is usually a little lower than its fellow, and, owing to the tonic action of the muscles on the healthy side, is drawn over in that direction.

When Bell's paralysis is due to disease situated within the skull various other complications are liable to be associated with it; and our diagnosis of the seat of the disease will be mainly determined by the nature of these complications. Thus, if the disease be within or near the internal meatus, the auditory nerve is likely to be involved and deafness to be produced; if it implicate the common nucleus of the sixth and portio dura, paralysis of the external rectus will go along with the facial palsy; and if it be irregular in distribution, or involve any considerable space, various

other paralyses, referrible to implication of the nerves originating in the floor of the fourth ventricle, are liable to be present.

Occasionally both facial nerves are simultaneously affected, or affected within a short time of one another—a condition which may involve some difficulty of diagnosis. The face then is smooth and expressionless, the eyes open and staring, the lips apart, and the patient is incapable of retaining fluids in the mouth or of pronouncing the labial letters.

The prognosis of paralysis of the portio dura will depend on the nature of the lesion to which it is due. That form of the disease which results from exposure to cold for the most part ends favourably, sometimes in a week or two, more frequently after four or five weeks, occasionally only after the lapse of some months. An element in the prognosis is the condition of the paralysed muscles as to faradic contractility; the more completely this has become annulled, the longer will recovery be delayed, and the greater is the fear that the paralysis may be incurable. M. Duchenne draws attention to the fact that not unfrequently permanent contraction of the muscles previously paralysed takes place, and that thus consecutive deformities are induced. This happens, he says, in those cases especially in which either spasms supervene in the paralysed muscles under the influence of faradism or other forms of excitation, or a rapid return of tonic force takes place in muscles remaining paralysed and irresponsive to faradism. The contraction affects sometimes one, sometimes several muscles. When it involves the lesser zygomatic, it curves and deepens the nasolabial line and gives an expression of chagrin; when the greater zygomatic, it elevates the commissure of the mouth and imparts an aspect of gaiety; when the quadratus menti, it depresses and everts the lip; when the orbicularis palpebrarum, it causes diminution of the palpebral aperture; if all the muscles are involved, the side of the face becomes wrinkled, as if by cold. At the same time that the muscles contract, or it may be subsequently, they usually recover their voluntary power; but that is not always the case, and the contracted muscles may remain permanently paralysed.

*Treatment.*—In the treatment of paralysis of the seventh pair from cold it is generally well (considering the serious results of permanent deformity) at once to adopt active measures; to apply a few leeches to the mastoid process, and to follow them up by fomentations, poultices, or equivalent applications. Subsequently blisters or other counter-irritants may be resorted to. If recovery do not follow these measures, electricity should be employed. Duchenne thinks it best, in cases where the faradic contractility has wholly disappeared, to delay the use of faradism until after the lapse of two or three weeks. He recommends the employment of a current with rapid intermissions, and that the muscles be directly and in turn excited. He points out that under this treatment the paralysed muscles often regain their tonic power, and the face its symmetry in repose, two or three weeks or more before there is any indication of the return of voluntary power; and that it is usually in the zygomaticus major that this power first returns—a fact which may be ascertained by making the

patient smile. When the muscles begin to contract, he recommends that the intermissions should be few and the sittings short and infrequent; and especially he recommends this if any of the precursory signs of permanent contraction manifest themselves, in order that such contraction may be prevented. Galvanism also is efficacious in restoring the paralysed muscles.

#### D. *Paralysis of the Spinal Nerves*

*Causation.*—Paralysis of these nerves may arise under various conditions; but we propose to refer only to those varieties which M. Duchenne speaks of as paralyzes from cold, and in which the paralysis is due to inflammation of the trunk of the affected nerve. These affections are not uncommon, and may be readily mistaken for ordinary rheumatism.

*Symptoms and diagnosis.*—The symptoms comprise pain and tenderness along the affected nerve, and febrile disturbance, together with the various consequences of disease involving mixed nerves: namely, on the one hand, burning or shooting pains in the course of its branches, and hyperæsthesia, followed by tingling and numbness; on the other hand, muscular paralysis, followed by speedy loss of faradic contractility and wasting. The muscular paralysis for the most part comes on later than the sensory symptoms. During the early period of the disease the temperature of the affected parts is augmented, later on it undergoes manifest diminution.

M. Duchenne singles out two forms of this affection for description, one of which he terms ‘deltoid rheumatism,’ the other ‘paralysis of the radial nerve.’ Affection of the spinal accessory is also not uncommon.

1. *Deltoid rheumatism* is essentially inflammation of the circumflex nerve. It is marked by the occurrence of violent neuralgic pains in the deltoid muscle, sometimes coming on in paroxysms, and augmented by any movement of the shoulder. In voluntary movements pain is especially excited in those fibres which are brought into contraction—a circumstance which will help to distinguish deltoid rheumatism from ordinary articular rheumatism. The symptoms may last for a few days only, or be prolonged for months. In many cases convalescence takes place without the occurrence of complications; but in some cases atrophy of the deltoid, or of a part of it, supervenes after the pains have continued for some time; and when at length, under these circumstances, the pains have subsided, the muscle continues atrophic, although retaining its voluntary and electric contractility. In other cases paralysis, attended with impairment or abolition of faradic contractility, supervenes.

2. *Paralysis of the musculo-spiral nerve* is sometimes referred to pressure on the nerve, occurring, for example, during sleep, but by M. Duchenne is attributed (like Bell’s paralysis) to exposure to cold, especially to exposure of the arm during sleep to a current of cold air, or to cold and damp. It generally comes on suddenly, without pain or tenderness, but with numbness and tingling, extending to the tips of the fingers. The paralytic symptoms have a close resemblance to those of lead-poisoning,

and, like these, comprise, as an essential feature, dropping of the hand and incapability of extending the fingers. The differences between them are, as M. Duchenne points out : first, that in paralysis from cold the paralysed muscles retain their electrical contractility unimpaired, whereas in lead-palsy this quality rapidly diminishes or disappears ; second, that the supinator longus, which never suffers in lead-poisoning, is invariably implicated in the present case. The following, as is shown by M. Duchenne, is the proof of implication of this muscle :—namely, that when the patient has placed his forearm in the position of semi-flexion and semi-pronation, and attempts to flex it more completely (the attempt being opposed), the long supinator, which in that position is the flexor of the forearm, can be neither seen nor felt to contract. As in lead-palsy, the flexor muscles of the forearm and hand and the interossei escape. Paralysis of the musculo-spiral nerve from cold is almost always followed sooner or later by recovery. In some cases, however, progressive wasting of the affected muscles comes on ; and occasionally, also, the opposing muscles and the interossei become manifestly enfeebled from want of use.

*Treatment.*—The value of electricity in the treatment of the above forms of paralysis is very great. When the deltoid pains are unattended with fever or local signs of inflammation, M. Duchenne strongly recommends the use of cutaneous faradism, effected upon a dry surface, with a feeble and slowly intermittent current. When, however, there is wasting or paralysis, faradism of the muscles or the interrupted galvanic current is especially indicated, both in the case of the deltoid and in that of the muscles of the forearm. In both cases, moreover, frictions, stimulant applications, and blisters are often serviceable. When there is distinct evidence of inflammation, the various forms of electricity are not only inefficacious, but injurious. The ordinary remedies for local inflammation are then called for.

---

#### XXIV. LOCAL FUNCTIONAL SPASM AND PARALYSIS, WRITER'S CRAMP, WRY-NECK, HISTRIONIC SPASM, &c.

*Definition.*—The affections here referred to are limited to single muscles, or parts of muscles, or to groups of muscles, and occur only or mainly at the time when certain accustomed specific actions in which they are engaged are in process of performance—the affected muscles apparently acting normally under all other conditions, and in other respects seeming perfectly healthy.

*Causation.*—The causes of these functional derangements are exceedingly obscure. They are, however, for the most part induced by the long-continued exercise, in special motor combinations, and the consequent fatigue, of the muscles which afterwards become affected.

*Symptoms and diagnosis.*—The most common of the affections included in the present group are those which are known in this country as 'writer's cramp' or 'scrivener's palsy,' 'spasmodic torticollis' or 'wry-neck,' and 'histrionic spasm.'

1. *Writer's cramp* affects, as its names imply, those who are engaged in writing, and more especially those whose avocations compel them to write for many hours a day continuously for long periods of time. It generally commences with a sense of fatigue or pain in certain of the muscles of the hand or forearm, which comes on shortly after the patient has begun to write. This condition increases slowly until pain or weariness attends all his attempts to write, and compels him to rest for a time or to desist altogether. Sooner or later, and sometimes from the very commencement, some spasm or loss of power, coming on only when the patient is engaged in writing, seizes certain of the muscles which he is exercising, and renders his handwriting tremulous or jerky, or arrests his operations completely. In the earlier stages of the disease, the patient sometimes resists its influence with more or less success. But its almost inevitable tendency is to go on from bad to worse, until at length the use of the pen becomes impossible. In some cases patients have learnt to write with the left hand; but in many of these, unfortunately, this hand has after a while become affected similarly to the other.

The affection is sometimes paralytic, the patient suddenly losing power over certain muscles, and dropping the pen from his hand; in most cases it is spasmodic, the muscles causing tremulous or choreic movements, or sudden flexion, extension, or rotation. Different muscles are affected in different cases. In some instances they are the extensors and flexors of the index-finger; in some the interossei of the second and third fingers; in some the muscles of the thumb; in some the supinators of the hand. Occasionally the muscles of the hand and forearm are all involved. In some cases the spasm or paralysis commences in the deltoid or other muscles of the shoulder; and in some it extends from the muscles of the hand and arm to those of the head and neck and trunk. As a rule a sense of fatigue or pain accompanies the functional motor disturbance, but occasionally the patient complains of muscular cramp or of neuralgic pains. However extreme the paralysis or spasm becomes, the muscles retain their functional activity for all other movements than those which have induced them; but there is for the most part distinct loss of muscular power.

2. *Spasmodic wry-neck* is an affection of adult life, and of either sex. It comes on for the most part insidiously with uneasiness or pain in the affected side, and a tendency to jerk the head as though to relieve some feeling of discomfort. By degrees the uneasiness increases, the spasmodic movements become more constant and more violent, and the head is habitually carried on one side. At first the patient can temporarily restrain his spasms by a voluntary effort, and temporarily hold his head erect, or he can counteract the spasmodic contraction of the affected muscles by the voluntary action of the healthy muscles of the opposite side. But after a while the head and neck become permanently twisted, and the clonic spasms which accompany this twisting are beyond even temporary control. The spasm of the muscles of the neck is apt to become associated with similar spasm of the facial muscles or of those of

mastification, or of those of the shoulder or arm. In the great majority of cases the spasms cease during sleep, or whenever the head is supported.

The muscles which are affected differ in different cases. In some instances they are those which rotate the atlas and skull upon the axis, and the movements of the head are those of simple rotation. Sometimes it is the *splenius capitis* which suffers; in which case the head is inclined downwards and backwards towards the affected side, the face at the same time rotating towards the same side, and the skin of the side of the neck being thrown into deep transverse folds. Sometimes it is the clavicular portion of the *trapezius* which is implicated; in which case, as in the last, the head is inclined downwards towards the affected side, and thrown somewhat backwards, but the face is rotated towards the opposite side. If the fibres of the *trapezius* which are attached to the shoulder also are involved, the shoulder will be distinctly elevated. Sometimes the *sternomastoid* suffers; in which case, as when the *trapezius* is contracted, the head is inclined towards the affected side, and the face is rotated towards the opposite shoulder; but, contrary to what happens in either of the other cases, the head is thrown forwards. Although the several muscles just named may be affected separately, it is more common to find groups of muscles implicated. But the affected muscles can generally be readily recognised not merely by their effect on the movements of the head, but also by their contraction, rigidity, and spasmodic action.

8. Among examples of other similar conditions we may quote the following, chiefly from M. Duchenne: A tailor whenever he had made a few stitches suffered from violent rotation of the arm inwards, in consequence of contraction of the *subscapular* muscle. A fencing-master, whenever he put himself into the posture of defence, was seized with rotation of the arm inwards and violent extension of the forearm. A turner, whenever he attempted to work the lathe with his foot, suffered from spasmodic contraction of the *flexors* of the foot upon the leg. A gentleman, who also suffered from writer's cramp, became subject, when he attempted to read, to contraction of the *rotator* muscles of the head, which carried his head to the right. A literary man, who had been employed for some years in deciphering manuscripts, suffered after a while from double vision, coming on a few seconds after he had fixed his eyes intently on any object; the defect was due to spasmodic contraction of one of the *internal recti*. A student, who had overworked himself, became the victim of a strange affection which rendered reading impossible, and finally impelled him to commit suicide. As soon as he began to read he was seized with a painful constriction of the forehead, temples, and eyes, during which the eyebrows were elevated by spasmodic contraction of the *frontales*, and the eyes closed by the powerful action of the *orbiculares palpebrarum*. Pianists are liable to the same affection as writers are. Singers occasionally become incapable of singing from involvement of the *laryngeal* muscles; soldiers of marching from implication of the *peroneus longus*. In some cases the spasms affect the muscles of expression (*histrionic*

spasm), in some the platysma, in some the muscles of mastication, and in some those of respiration.

*Pathology.*—The pathology of these functional affections is very obscure. Most writers believe that the primary fault is in the nervous centres; but Dr. Poore, in his able text-book of electricity, seems to prove conclusively that the disease is in many cases due to abuse of the implicated muscles, which ‘become tired out, and degenerate into a condition of chronic fatigue or irritable weakness;’ and he shows also that, contrary to the general belief, the affected muscles are absolutely weaker than their healthy fellows, and that their faradic irritability is diminished.

*Treatment* has not usually proved satisfactory. In Duchenne’s hands faradism failed absolutely. Dr. Poore, however, has latterly obtained great success by the employment of the continuous current in combination with rhythmical exercise of the enfeebled muscles. His mode of using the current in writer’s cramp is as follows:—‘One pole (the positive) is placed, let us say, in the axilla, and the other over the ulnar nerve, just where it leaves the edge of the biceps muscle *en route* for the olecranon. The strength of the current is short of that which causes muscular contractions, but is just sufficient to make the patient conscious of a tingle in the end of the little finger when the circuit is made or broken. The patient is then made to exercise the interossei by separating and approximating the fingers rhythmically.’ The nerve to be galvanised and the muscles to be exercised will of course differ in different cases. Liniments and douches may also be employed; and tonics are generally indicated. But in all cases it is of the highest importance for the patient to abstain in a greater or less degree from all those habitual actions with which the muscular default is especially linked, and never to attempt to overcome it by violent efforts. Rest is essential.

---

## XXV. NEURALGIA. TIC DOULOUREUX. SCIATICA

*Definition.*—By the term neuralgia is meant pain, for the most part paroxysmal, occurring in the course of nerves and in their area of distribution.

*Causation.*—Neuralgia is the result of numerous different conditions. It may depend on sclerosis or degenerative affections of the nervous centres, more especially of the cord and medulla oblongata; on injuries to nerves, due to contusion, laceration, or the impaction of foreign bodies; on pressure, such as may take place when the bony channels through which certain nerves pass become contracted from any cause, or when nerves are pressed upon by tumours or other adventitious masses; or on the implication of nerves in disease, as, for example, when they are involved in rheumatic or other inflammations, in syphilitic gummata, or in carcinomatous or other tumours. In some cases it appears to depend upon, or to be connected with, certain constitutional conditions, such as the malarial cachexia, anæmia, and hysteria. In a considerable number

of cases no cause whatever, local or constitutional, can be discovered. Neuralgic affections are said to be hereditary. This is no doubt true of specific forms, such as megrim, and possibly of tic, but can scarcely admit of satisfactory proof in respect of the heterogeneous cases which make up the great bulk of ordinary neuralgiæ.

It need scarcely perhaps be pointed out that neuralgic pains, which are sometimes of extreme intensity, attend a large number of diseases which have already been discussed: among others, tabes dorsalis, spinal caries, and more particularly carcinoma of the vertebræ or pelvic organs, certain inflammatory affections of deep-seated parts, such as abscess of the liver, calculous pyelitis, and hip-joint disease, and a large proportion of the cases of zona or herpes zoster.

Lastly, it is important to bear in mind that the lesion or local condition causing neuralgia may exist in the course of the implicated nerve, or in the spinal cord or brain, or (as above pointed out) may occupy some remote part from which it acts indirectly.

*Symptoms and progress.*—Neuralgia is characterised essentially by the occurrence of pain in the course and distribution of some one or more of the sensory nerves. The pain varies in character: it may be tingling, aching, burning, boring, crushing, cutting, stabbing, darting; it may be continuous, but usually occurs in sudden lightning-like shocks, which come on either singly or in paroxysms made up of a larger or smaller number of such shocks; and even when it is continuous, it is usually attended with exacerbations presenting more or less of the latter character. The pain varies also in intensity; in its severest paroxysmal form the patient's sufferings are horrible—sometimes he raves and stamps like a madman, sometimes utters half-suppressed groans, sometimes screams aloud, but under any circumstances is so absorbed in the intensity of his sufferings that he appears almost unconscious of everything which is going on about him; on the other hand, it may consist in nothing more than a little tingling, creeping, or burning. This is often the case during the inter-paroxysmal stage of those cases in which there is never entire cessation from pain; and such sensations often constitute the commencement of each paroxysmal attack.

It commonly happens that tenderness or hyperæsthesia is associated with neuralgia; there may be tenderness along the course of the affected nerve; or there may be general tenderness in the area of its distribution, or spots of special tenderness scattered here and there upon that surface. It is a fact of considerable importance, first established by Valleix, and since confirmed by numerous observers, that in neuralgia there are generally, if not always, specially painful spots, which are more or less characteristic for each nerve that may be involved, and are determined mainly by the emergence of the nerve or of some of its branches from a bony canal, or by their passage through some dense fascia. Trousseau insists that one of these painful spots is the spinous process of that portion of the spine from which the painful nerve escapes. The neuralgic paroxysm may often be induced by irritation of the hyperæsthetic parts,

or even by touching them ; on the other hand, firm pressure on them may relieve or avert it.

Anæsthesia, again, is not unfrequent in connection with neuralgia. Sometimes impairment of tactile sensibility or discrimination goes along with considerable tenderness or hyperæsthesia. But absolute loss of sensation in the affected area occasionally supervenes after a time.

The sudden darts of intense pain which so commonly attend neuralgia are generally associated with sudden reflex movements or twitchings of the part affected ; if the toe be attacked, the leg is momentarily drawn up by an uncontrollable impulse ; if the finger, the arm ; if the face (as in ordinary tic douloureux), spasmodic twitching of the muscles of the painful region occurs. These convulsive movements may vary from mere twitchings of the muscles to spasmodic contractions of considerable force.

The above phenomena are apt to be complicated with other local manifestations. In many cases the affected surface becomes congested during the occurrence of the paroxysm ; and not unfrequently obvious dilatation of the arteries and veins, both in and leading to or from the implicated region, takes place, attended with painful throbbing. In connection with congestion, there is apt also to be some temporary modification of function in the affected area, such as arrest or increase of secretion, which is especially obvious if the conjunctiva or the mucous membrane of the nose or mouth be the part involved.

Further, the various nutritive lesions, especially erythematous and herpetic eruptions, which have previously been referred to affections of the sensory nerves, are all apt to occur in connection with neuralgia. Occasionally also the hair over the affected region turns temporarily or permanently white.

An interesting feature of neuralgia is the tendency to shift which it presents in many cases. Thus in trifacial neuralgia the paroxysmal attacks not unfrequently wander either from day to day, or it may be at distant intervals, from one branch of the nerve to the other branch ; the pain may even pass over to the great occipital nerve or to branches of the cervical or brachial plexus.

Another important point connected with neuralgia, and one indeed which has been regarded as inseparable from true neuralgia, is its unilateral or unsymmetrical character. This characteristic, however, is not universal, and occasionally both arms or both legs are symmetrically and equally affected.

In a large proportion of cases neuralgia is essentially intermittent ; the pains come on in paroxysms lasting probably from a second or two to a minute, rarely longer, which recur every five or ten minutes, day and night, or manifest themselves at longer and more or less irregular intervals. Occasionally they remit for weeks or months together.

The general state of health of neuralgic patients presents considerable diversity, yet it is important, in reference both to prognosis and to treatment, to pay attention to this subject. Thus in some cases we find the patient anæmic, in some hysterical, in some labouring under the conse-

quences of old syphilis ; sometimes he is rheumatic, sometimes gouty, sometimes he is suffering from the effects of malarious poison. But in a considerable number of cases, and these are often the most severe and intractable, no general morbid condition can be discovered beyond that which the persistent neuralgia itself induces. In these cases the disease is not unfrequently incurable.

Neuralgia may attack any of the sensory nerves, as well those supplying the viscera as those distributed to the skin. Among the former class may especially be named neuralgiæ of the heart, stomach, kidneys, uterus and ovaries, testes, and mammæ. Among the latter class the more important probably are trifacial neuralgia or *tic douloureux*, and sciatica.

1. *Tic douloureux*, or, as Trousseau terms it, 'epileptiform neuralgia', is at once the most severe and the most typical variety of neuralgia. It comes on in adult life, and is for the most part of lifelong duration. Its causes are obscure: sometimes it is referred to carious teeth, sometimes to exposure to cold, sometimes to gastro-intestinal irritation, sometimes to old age or failing health or malarious influence. The neuralgic phenomena involve the branches of the fifth nerve of one side. In some cases it is the first division, in some the second, in some the third, occasionally the whole nerve ; or it may be that certain portions only of its divisions are involved. The pains, moreover, are apt to shift from time to time from one division to another, or from certain fibres to certain other fibres. They vary in character as other neuralgic pains vary ; but usually are burning or shooting, and occur in sequences of sudden electric-like shocks. They vary also in intensity, from a mere sense of warmth or tingling to paroxysms of the most intense agony. They sometimes come on at rare intervals ; sometimes, on the other hand, occur every few minutes, night and day, and are then apt to be brought on by any movement of the affected parts, by pressure, by sudden shock, or even by a breath of cold air. Consequently, in cases in which the second or third division is involved, the patient finds it impossible to masticate, and almost impossible to take nourishment by the mouth. Under any circumstances the severity and frequency of the paroxysms are apt to vary from time to time ; and occasionally, even in severe cases, the attacks intermit for comparatively short periods. In aggravated cases the paroxysms of pain are often attended with spasmodic contractions of the muscles of the affected region. Sometimes the patient smacks his lips, or chews, or executes other movements which are apparently voluntary, and are performed with the object of relieving pain. More frequently he rubs his face during the paroxysms with either his hand or a handkerchief, or a pad that he carries in his hand for the purpose. This constant rubbing not unfrequently wears down the hair of the affected side—the whisker, the beard, the hair in the neighbourhood of the temple—which then appears as if kept close shaven ; occasionally it even modifies the form of the side of the face. Further, the frequently repeated spasmodic action of the muscles of the affected side produces after a while a permanent curiously wrinkled condition of the surface.

Tic douloureux, unbearable though it appears to be, does not tend directly or necessarily to shorten life. Patients nurse their agony for many years. The only ways in which it can be regarded as inimical to life are by the difficulty which it occasionally opposes to the ingestion of food, and by driving the patient to suicide.

2. *Sciatica*.—This is one of the most common varieties of neuralgia. It frequently arises from exposure to cold, but may be due to many other causes; it is occasionally attended or followed by some degree of anæsthesia, and occasionally, but mainly when due to structural disease, leads to wasting of the muscles. The pain is of true neuralgic character, and is greatly aggravated by movement of the implicated limb, or by pressure. It is in many cases exceedingly persistent and difficult of cure.

*Treatment*.—In dealing with cases of neuralgia it is always of great importance to ascertain, if possible, the cause on which it depends, and then, if it be within our competence, to obviate or remove it. If, for example, the pain be traceable to the influence of the malarious poison, quinine or arsenic is indicated; if it be connected with anæmia, iron is probably the best remedy; if it be a consequence of exposure to cold, of rheumatism or of gout, the treatment suitable for these conditions should be employed; if it be referrible to syphilis, iodine and mercury are most likely to be serviceable; and further, if it depend on the existence of some local morbid process compressing or otherwise involving the nerve, our treatment must vary accordingly.

But in a large number of cases no such hints for treatment are afforded us; we can then, so far as general treatment is concerned, only deal with them empirically. Among remedies which, under the circumstances, have been found useful, may be enumerated iron, arsenic, quinine in large doses, salicylate of soda, oil of turpentine, chloride of ammonium, phosphorus, croton-chloral hydrate, antipyrin, aconite, Indian hemp, belladonna, and opium. Of these arsenic and Indian hemp are often of great service, but opium, or its alkaloid, morphia, is on the whole by far the most valuable. Indeed, the severest cases of tic, and of similar forms of neuralgia in other parts, often find relief only from large and repeated doses of this drug, which may then be given by the mouth, or preferably by subcutaneous injection. If given by the mouth, it may be necessary at length, having begun with small doses, to administer as much as from twenty to sixty grains of morphia daily. Alcohol is not unfrequently serviceable in relieving pain. Cases of the less severe forms of neuralgia are occasionally cured by a few glasses of wine, or by a tumbler of strong brandy and water.

Local medication is often very valuable. Of course the several narcotics which have been enumerated, especially morphia and atropia, may be injected subcutaneously at the seat of pain. But, besides this, the application to the surface, or the inunction, of opium, belladonna, or aconite often gives relief. The most valuable of these applications is aconite in the form of the unguentum aconitiæ. Counter-irritation also is frequently of much benefit, more especially by means of blisters, issues, the actual

or galvanic cautery, and acupuncture. Electricity is especially valuable. Duchenne employed cutaneous faradism, rendering the affected surface dry by dusting it with some powder, and then applying to it for a minute or so faradism of considerable strength, and repeating the process from time to time according to circumstances. But the continuous current is much more efficacious. In this case well-wetted sponges must be used, and the current employed must be of no greater intensity than the patient can readily bear; and as has before been pointed out, the origin of the affected nerves should be included between the rheophores, of which one should be moved over the painful region, and especially applied to the painful points. Moreover, here, as in the other case, the applications should be of short duration, and frequently repeated. Lastly, division of the affected nerve or stretching it has often been practised, especially in cases of *tic douloureux*. It cannot be asserted that either procedure ever absolutely cures the neuralgia; but there is no doubt that it very often effects a temporary cure—a cure lasting occasionally for a few weeks or even for several months.

## XXVI. MADNESS. (*Insanity* <sup>1</sup>)

### *Definition.*

By the term insanity or madness is understood a state of mind in which its normal faculties—namely, the feelings, the intellect, and the will—are partially or generally enfeebled, exalted, or deranged; and in which necessarily the mental disease is reflected in the speech, the action, and the conduct, and very generally functional disturbances of the organs of sensation, the voluntary muscular system, and the visceral organs are present.

The above definition includes many mental conditions which are not ordinarily regarded as madness; such as the delirium which occurs in febrile and other disorders, and that arising under the influence of alcohol and other toxic agencies; hysteria, at any rate in many of its phases, and conditions of overpowering passion into which persons presumably healthy occasionally fall; and those forms of mental aberration, such as general paralysis of the insane, idiocy, senile dementia, and the like, which are due directly to obvious organic lesions of the central nervous organs.

It seems to us, however, that although some of these forms of mental disturbance or disease are not such as need restraint, or are simply transient conditions, or are mere incidents of grave corporeal disorders, and on many grounds therefore are not madness in the popular acceptance of the word, they are all properly included in the scientific meaning of the term.

As is usually done, we shall omit from our description of insanity the

<sup>1</sup> In writing this article the authors who have been chiefly consulted, and whose language has here and there been employed, are Griesinger, Marcé, Maudsley, and Bucknill and Tuke.

delirium of febrile and other diseases, acute toxic forms of delirium, ordinary hysteria, and simple outbursts of passion ; but we shall embrace in it paralysis of the insane, idiocy, senile dementia, and insanity due to the development of cerebral tumours.

### *Causation.*

1. *Predisposing causes.*—*a.* The question of the influence of race or nationality in the causation of madness has been largely discussed. But the subject is a complicated one ; for it necessarily comprises, not merely the simple influence of race, but the collective influence of all those conditions which contribute or have contributed to the formation of the national character, such as religion, politics, warfare, occupation, habits, intellectual progress, and civilisation. And the general result of inquiries with regard to it has been to show, not that there is any appreciable difference in respect of proneness to insanity among races of men *per se*, but that insanity is especially apt to become rife during great national or religious crises, and under other conditions of wide-spread emotional excitement ; and that, on the whole, the lower nations are in the scale of education and civilisation the less the frequency of insanity among them. *b. Hereditary predisposition* plays an important part in the production of insanity. According to Dr. Maudsley the proportion of distinctly hereditary cases to others is not lower than one-fourth, if not so high as one-half. But, although the general truth of this proposition has been established beyond dispute, it is for many reasons difficult to give it exact numerical expression ; especially it is difficult to decide how far back and how wide amongst direct ancestors and collateral relations such influences may properly be sought. Again, although actual insanity amongst parents or relations is the most frequent cause of hereditary predisposition, there is reason to believe that other neuroses, more especially epilepsy, hysteria, and a suicidal tendency, have a like influence ; that genius and insanity are often distributed in the same family ; and that drunkenness in parents is apt to beget insanity in children. It is said that the frequent intermarriage of close relations tends sooner or later to a like result. Esquirol observed, and his observation has been confirmed, that insanity descends from the mother more frequently than from the father, and to the daughters in larger proportion than to the sons. *c. Education* has an undoubted influence in relation to insanity—a judicious training tending to strengthen minds which have an inherent weakness and proclivity to it, while an injudicious training may sow the seeds of mental disease in those who are free from all original taint. The subject is a wide and important one ; but it is sufficient to remark here that long-continued harshness, cruelty, and repression in early childhood, the persistent endeavour to cram the undeveloped mind with abstruse or unsuitable knowledge, or to instil with terrifying iteration the repulsive dogmas of a narrow Christianity, the foolish and indiscriminate yielding to all the whims, selfish desires, and passions of childhood, may each in its own way exert an evil influence over the future mental welfare of the unfortu-

nate victims. *d. Social position and occupation* are of doubtful efficacy in causing insanity, excepting is so far as the different conditions included under these terms imply exposure to associated influences which are themselves productive of insanity, such as drunkenness and other forms of debauchery, mental strain, emotional disturbance, and the like. *e. Sex.* There is no sufficient reason for believing that one sex is more liable to insanity than the other. At the same time the exciting causes of insanity act with different relative frequency in the two cases; and there are marked differences in the degree in which its several forms prevail among them. Especially it may be noted that general paralysis, which is common in men, is comparatively rare in women. *f. No age* can be regarded as exempt from liability to insanity. It is rare before puberty; yet all forms (excepting general paralysis) are occasionally met with during this period of life. It becomes much more common between 16 and 25; but arises mainly between 25 and 45 or 50. In women it is apt to come on with marked frequency about the climacteric period. Subsequently the tendency to it declines. In these remarks relating to the influence of age, idiocy has been excluded from the one end of the scale and senile dementia from the other.

2. *The exciting causes of madness* are of two kinds, namely the moral or psychical, and the physical.

*a. Moral causes* are generally held to be the most fertile sources of the disease. *i.* But mere intellectual exertion, however intense or however much prolonged, rarely produces it. *ii.* And even the expansive passions—ambition, overweening vanity, immoderate joy, and the like—are almost equally inefficacious in this respect; and, when they cause it, evolve it usually by slow degrees, and, as Dr. Maudsley observes, ‘as a gradual development or exaggeration of a particular vice of character.’ *iii.* It is the depressing emotions which are mainly instrumental in causing insanity; and Pinel was so convinced of the truth of this that the first question he put to a new patient was always, ‘Have you suffered vexation, grief, or reverse of fortune?’ Fierce anger, unrequited love, jealousy, prolonged anxiety, the distress arising from loss of fortune, disappointed ambition, grief at the sudden death of some dear relative or friend, remorse, hatred, fright, religious depression, the sense of being unequal to responsibilities which have been incurred, may be adduced as examples of the kinds of emotion here referred to. The effect of such emotions may be sudden, as when they act by shock; or slow, in which case either they produce a gradual intensification of peculiarities already present in the patient’s character, or they involve a gradual morbid change in one or more of the viscera, to which change, rather than to the emotional disturbance directly, the mental disease is due.

*b. The physical causes of madness.*—*i.* Of these, alcoholic intemperance is doubtless the most important. The symptoms of simple inebriation are closely related to those of insanity; delirium tremens is itself a variety of insanity; and further, the habit of drinking to excess produces irritability, vacillation, and other mental phenomena which indicate deteriora-

tion of mind. But independently of these conditions, partly it may be from the emotional disturbances which are incidental to alcoholism, partly from the direct influence of alcohol in the production of disease (especially induration of the surface of the brain), the abuse of drink is a pregnant cause of insanity. It operates chiefly in men; and is a prominent cause of general paralysis of the insane. Intemperance in opium, absinthe, Indian hemp, or other narcotics, is also liable to induce insanity. ii. Sexual excesses, and especially self-abuse, are well-recognised exciting causes. Self-abuse is particularly efficacious in this respect, partly from the early age at which it generally commences, partly from the excessive frequency with which it is apt to be indulged in, but mainly, probably, because of the moral distress which a persistence in the habit always occasions. iii. Many affections of the nervous system, general or local, are often associated with insanity, either as its cause, or as the concurrent consequence of some obscure morbid state. Insanity often complicates epilepsy; epilepsy not unfrequently terminates in mental derangement, and more especially in dementia; and acute maniacal attacks are liable to be associated with or to replace the epileptic seizure. Not only is a peculiar mental condition closely allied to insanity often present in hysteria, but hysterical patients are liable to attacks of acute mania, and to chronic forms of mania and melancholia. Chronic diseases of the brain or cord in large proportion are attended, sooner or later, by insanity, and more especially by chronic mania or dementia; among these may be included syphilitic and other cerebral tumours, sclerosis of the nervous centres, and the sequelæ of apoplectic effusions, and of injuries to the skull. Many cases also are recorded in which insanity appears to have been induced by disease or injury of nerves, and even by powerful impressions on the organs of special sense. iv. Other local conditions liable to cause insanity are those connected with the female reproductive organs; the most interesting and important of which are related to the puerperal state. It is somewhat rare for insanity to come on during pregnancy; on the other hand, it sometimes disappears on the supervention of pregnancy. It is mainly in connection with parturition that insanity arises. Sometimes there is an acute outbreak of short duration during the very act; sometimes it occurs during the first fortnight after confinement, and is then generally attributable to some inflammatory or septicæmic complication; sometimes it supervenes at a later period, independently of any local or other disease that can be detected, and under such circumstances is apt to be chronic, though for the most part curable, and in the form of melancholia or mania, not unfrequently associated with nymphomania. Outbreaks of insanity occasionally attend the menstrual flow, and are sometimes induced by the suppression of that discharge. v. Many other affections besides those which have been discussed are liable to be complicated by, or to cause, insanity; amongst which may be enumerated diseases of the heart and lungs, diseases of the abdominal organs and kidneys, tuberculosis, gout, chronic anæmia, and suppressed discharges of various kinds. But the most interesting in this respect probably are

acute, and especially the acute febrile, diseases. Patients in these cases are sometimes attacked with sudden and furious maniacal excitement, which may last only for a few hours, or a few days ; but not unfrequently the attacks, which are then either melancholic or maniacal, become chronic, and, although generally curable, may need to be treated in an asylum. These outbreaks occur for the most part during the subsidence of the disease, or even during convalescence. They are observed mainly in pneumonia and rheumatism, in enteric and typhus fevers, and in some of the exanthemata. They occur, too, in ague, in which case paroxysms of temporary insanity are apt to replace the ordinary febrile paroxysms. Acute anæmia, such as results from sudden and copious losses of blood, is sometimes attended with an outbreak of acute mania.

### *Symptoms and Progress*

A. *General description.*—In order rightly to understand the pathology of the brain, as that of all other organs, the necessity has long been recognised of regarding the morbid structures as mere modifications of the healthy structures, and to seek in the normal development of the healthy parts the clue to the abnormal development of the parts which are diseased. So, if we would rightly apprehend the pathology of the mind, as that of functional disturbance of other organs besides the brain, we must accept the fact that its normal actions are simply modifications of its healthy actions, and that the secret of their evolutions is to be learnt from a careful study and comparison with them of the natural phenomena of the mind.

The mind from the moment of birth, at which time it is a blank page, is constantly, through the instrumentality of the organs of sense, receiving impressions which paint themselves more or less vividly upon it. The impressions or perceptions which are thus made are stored up and remain henceforth the property of the mind, to be utilised by it, to be recalled from time to time voluntarily or involuntarily, to be analysed, compared, combined, rearranged, and so to contribute to the formation of new and complex ideas—of a subjective world which reflects but idealises the world without. Intimately associated with the perceptions and ideas which thus throng the mind are the mental qualities which give them their tone or colour, and the purely intellectual functions by whose cold light they are examined and compared. By the former are meant the senses of pleasure and of pain, the moods, the feelings, the passions, the moral qualities, which accompany perceptions and ideas, or are called forth by them, and which pervade and leaven them, or put them in special aspects, or endow them with qualities which are not inherent in them, but are the reflexes of the mental conditions whence they are derived. The purely intellectual functions comprise memory, reason, and imagination, the powers by which we recall the perceptions and ideas which are stored up in the mind, by which we analyse, compare, and form judgments, and by which we rearrange our ideas, invent, and create. The springs of action have their sources in the functions which have here been con-

sidered. Impressions received in the perceptive centres, and even revived impressions, induce involuntary reflex actions for protective and other purposes. Under the influence of the various moods and passions not only do the features and the general demeanour reveal with more or less accuracy the dominant emotional condition, but their subject is not unfrequently driven to perform acts, it may be of heroism, it may be of crime, to which reason alone would never have prompted him, or from which it would have restrained him. Above all, presiding over all, is the will, at any rate that higher element of the will, by the exercise of which we give attention to and regulate our mental operations, and which governs, directs, and restrains the more or less wayward and uncertain impulses to action which originate in ordinary reflex conditions or in emotional disturbances.

It need scarcely be added that the due relation of the mind to the external world requires, on the one hand, that the organs of sense shall be efficient and in uninterrupted connection with the perceptive centres, and, on the other hand, that the motor cell-groups for co-ordinated actions, together with the subordinate motor apparatus, shall have their normal relations with the supreme centres of action.

In mental disease, or insanity, there is necessarily disturbance of one or more of the functions which have here been enumerated; and consequently we have to consider, as factors of insanity, 'disorders of sensation,' 'intellectual disorders,' and 'disorders of movement.'

1. *Disorders of sensation.*—The sense of illness, or that of well-being when illness is present, may be referred to this head. It is remarkable that in many cases of insanity the patient is quite free from all feeling of bodily ill-health, and on this account will often protest against medical treatment. There are other cases, however, notably cases of hypochondriasis, in which the sense of illness is not only present, but profoundly exaggerated; and generally when convalescence is in progress the patient suffers from depression, fatigue, and other symptoms which satisfy him that he is ill. Anæsthesia and analgesia are often observed in melancholia and dementia, but above all in general paralysis; and these conditions may be general or limited to certain parts. But, in most lunatics, sensation remains unaltered. There may even be hyperæsthesia.

The most interesting sensory disorders, however, are those which are known as illusions and hallucinations—the former term signifying the false perception of impressions made upon the organs of sense, the latter term signifying subjective sensory perceptions which 'are projected outwards, and thereby become, apparently, objects and realities.' It is clear that there is a real difference between hallucinations and illusions, and yet it is often difficult or impossible to distinguish between them. Thus, in delirium tremens, when the attendants, articles of furniture, and even shadows, are taken for fiends or wild beasts, or muscæ volitantes due to disturbance of the retinal circulation are transformed into beetles, butterflies, or gold and silver coins, the patient is the victim of illusions; but when he perceives similar things while nothing in the world around or in

his organs of sense furnishes, so to speak, his mind with an excuse for seeing them, he suffers from hallucinations. Both illusions and hallucinations may involve any or all of the senses. In the following paragraph, we shall speak of them as if they were identical.

Hallucinations of sight are probably more common than those of any of the other senses. They are seen, in different cases, by night, by twilight, or by day; they may be vivid or shadowy; they may be of short duration or persistent, or may come and go; and they necessarily vary in character—in some instances animals, in some human beings, in some friends long dead, in some devils, in some angels, and in some panoramas crowded with life rising before the patient; and they are shocking, terrifying, or agreeable, according to circumstances. Hallucinations of hearing are rather less common, and on the whole of graver augury, than those of sight. They are especially common in melancholia and chronic mania. The patient generally hears voices, to which he listens, with which he converses, which he quarrels with or obeys. These voices sometimes talk nonsense, frequently they upbraid or insult, or utter profane or obscene language, or revile the sufferer's friends or relations, or tempt or command him to evil deeds. They often seem as distinct as the real voices which are uttered around him, and appear sometimes to come from articles of furniture or particular spots, sometimes to reach him from a far distance, and maybe by telephonic agency, and sometimes to be internal voices or voices without sound. Occasionally the patient hears discordant inarticulate noises, or strains of music. Hallucinations of smell, taste, and common sensation are not unfrequent. As regards smell and taste, the impressions on the perceptive centres are almost always of a disagreeable or offensive kind. Hallucinations of common sensation lead to the belief that animals are crawling over the skin, or that galvanism is being applied, or that frogs, snakes, birds, or the arch-fiend himself is present in the chest, abdomen, or head. They are especially common in relation to the reproductive organs in both sexes. Hallucinations of several senses are often present at the same time; and, when thus associated, and in any degree concordant, naturally tend to confirm to the patient the objective reality of his false impressions.

But, although illusions and hallucinations are amongst the most striking and important indications of insanity, their presence by no means necessarily implies the insanity of the sufferer. Many cases have been recorded (and such cases are not uncommon) in which persons, in all other respects mentally sound, have seen casually, or have been troubled more or less persistently with, hallucinations of sight and even of hearing, but who have been able by reason and observation to satisfy themselves of the unreality of their abnormal sensory impressions. Nor even does it necessarily follow that, because a patient believes in the reality of the phantoms which present themselves to his senses, he is to be regarded as insane. The natural credulity of many persons, the belief in which many have been brought up in the existence of ghosts, in the possibility of the reappearance of the dead, and in the naturalness of

supernatural occurrences, and the inaptitude of most persons for scientific investigation, make them ready believers in the objective reality of the phantasms which arise in their perceptive centres, especially if, as is most probable, the hallucinations have some obvious relation to their prevailing sentiments or beliefs.

2. *Intellectual disorders*.—These comprise perversions of feeling, or of the affective functions, derangement of the intellect or of the ideational functions, and disturbances of the will.

a. Esquirol declares ‘moral alienation to be the proper characteristic of mental derangement;’ and says, ‘there are madmen in whom it is difficult to find any trace of hallucination, but there are none in whom the passions and moral affections are not perverted or destroyed. I have in this particular met with no exceptions.’ The accuracy of the opinions here expressed is generally admitted. The earliest indication of insanity in the great majority of cases is, not the occurrence of hallucinations or perversions of the reasoning powers, but some change in the patient’s feelings, a sense of sadness, perplexity, restlessness, dissatisfaction, or irritability, a feeling of buoyancy, extravagant joy, or recklessness, a condition of dulness, apathy, or utter indifference, which pervades the patient’s thoughts, which modifies his relations to the world about him, especially perhaps to particular objects, and which reveals itself more or less obviously in all his actions. The phenomena here referred to are not such as would necessarily strike the casual observer; for among the many varieties of character presented by those among whom we dwell we not unfrequently meet with some which differ little, if at all, in their actual condition from the abnormal characters of insane persons. The main indications (apart from the supervention of other and more striking evidences of insanity) that such moral conditions are insane, are partly their extravagance, but especially the fact of their coming on in persons in whom an opposite or at any rate different character had formerly prevailed. Thus, it is not the fact of a man being in a desponding frame of mind, neglecting his affairs, and attempting suicide, or of his being a liar, a thief, or grossly indecent, or of his being quarrelsome and revengeful and attacking with fury those who thwart him, or of his being reckless in his speculations, and outrageously extravagant in his expenditure, which constitutes him insane; for such peculiarities of temper or of conduct are not uncommon in a greater or less degree among such as are altogether free from mental disease, and some at any rate may be developed temporarily under circumstances which are sufficient to explain their presence. But insanity is manifested when, without adequate cause, the man of hopeful disposition becomes despondent and miserable; the truthful, honest, and pure-minded Christian gives himself up to vicious practices; the amiable and considerate friend becomes quarrelsome and violent in his conduct; and the cautious and shrewd man of business loses his caution and shrewdness, and enters upon a course of wasteful expenditure and wild speculation. It is under the influence of such moral perversion that, without necessary delusion or obvious im-

pairment of judgment, hatred, suspicion, jealousy, ungovernable rage, and other passions arise, often directed against near and dear relations and friends, which drive their subjects to acts of violence and murder; and similarly under its influence that many persons are impelled to theft, arson, drunkenness, and other extravagant follies or crimes.

*b.* The intellectual functions are probably always to a greater or less extent impaired or perverted in insanity. Often the memory suffers. But in many cases, as for example in monomania, it is, or appears to be, unimpaired. And it is an interesting fact that, although occasionally no doubt patients on recovery from an attack of insanity forget in some degree or even absolutely all that occurred to them during their illness, they do in the large majority of cases retain a fair recollection of their experience, and are slow to forget injuries or kindnesses which they have received at that time. Again, madmen not unfrequently have a vivid recollection of the events of their former lives, while forgetting (perhaps from want of attention) circumstances which have recently occurred; while, on the other hand, former occurrences are sometimes blotted out, or become so hazy as hardly to be recognised as belonging to their own experience. These peculiarities attach especially to chronic mania and dementia. In a large number of cases, however, it is not so much that accumulated knowledge is effaced from the mind, as that there is a loss of the power of voluntarily recalling it, and that it is apt to come up casually and unexpectedly. Occasionally the memory appears to be preternaturally active.

The faculty of ideation becomes affected, and for the most part largely affected, during the progress of insanity. In some instances, as in melancholia, conceptions are slowly formed, and ideas present themselves sluggishly to the mind; in other cases, as for example in acute mania, they are developed tumultuously, and succeed one another rapidly, and the mind is kept in a constant whirl. The general character of the patient's ideas is largely determined by his prevailing mood, or passion; and hence in melancholia his ideas are for the most part gloomy and desponding; in mania, vivacious, humorous, grotesque. Further, there is often an obvious connection between the prevailing insane ideas, and vivid impressions that happened to be made on the mind immediately before the attack. When the ideas are sluggish, as they are apt to be in dementia and melancholia, they are often persistent, or tend to recur. This persistency of certain ideas or certain groups of ideas is especially characteristic of monomania. When, on the other hand, the ideas flow rapidly, they are less tenacious, and, although still largely determined by the patient's emotional state, are largely called up by the persons, things, and occurrences about him, and by whatever attracts his attention for the moment. Under these conditions, too, they are liable to follow one another without mutual connection, and to become incoherent. Incoherence, however, depends not only upon tumultuousness of ideas, but equally upon failure of ideas and general loss of mental power. It is not necessarily a paucity of ideas, or superabundance, or incoherence, or in-

appropriateness, or oddity, or fixity of them that constitutes insanity ; for many sane persons are characterised mentally by some one or more of these conditions, and all of us are liable to incoherence of thought and inappropriateness. But here, as in affective insanity, the answer to the question as to whether a patient is insane or not must depend largely on a comparison between his present mental condition and that which characterised him formerly. And especially much will depend on the point of view from which the patient regards his ideas, and on the influence which they exert over his conduct.

The reasoning powers are doubtless impaired in all cases of insanity. This is not always at first sight apparent ; for many lunatics, especially monomaniacs, argue with considerable skill, not only on general matters, but even on the subject of their delusions, for their belief in which they sometimes adduce the most plausible reasons ; and others, as for example persons suffering from acute mania, converse with no little brilliancy, making sparkling and witty observations, and being ready with repartee and sarcasm. In the former case, however, close observation will probably reveal manifest mental weakness, and especially an inability to appreciate or to meet arguments directed against their delusions. And in the latter case the readiness of retort and the vivacity of speech are associated with a total loss of power to pursue any train of reasoning, or even to sustain a connected conversation. But the failure of the reasoning powers becomes specially apparent when illusions, hallucinations, and vivid ideas take possession of the mind, and are accepted as objective realities or fundamental truths, and form at once the substratum and the motive of the patient's thoughts and actions—when, in fact, they become delusions and the foundation probably of a superstructure of further delusions. Delusions are often of slow growth, and, though constituting perhaps the most striking phenomena of insanity, for the most part appear secondarily, either to the moral disturbance which is generally the earliest symptom of mental disease, or to that phase of insanity which is characterised by hallucinations, and by undue slowness, or rapidity, or by perversion of ideas. The melancholic patient presents in the first instance a sense of profound depression ; and it is only subsequently that a definite delusion crystallises as it were out of this general feeling, and becomes the assigned cause of his mental condition. The patient, whose affective state is at first one of gaiety and restlessness, only at a later period acquires the expansive delusion that he is enormously rich, as strong as Hercules, a king of men, or God Almighty. And often, as we have shown, illusions and hallucinations, and it may be added insane ideas, are recognised for a time by the patient at their proper value, and are resisted and wrestled with by him, until probably at length his reason yields at discretion, and becomes their captive. It is of course mainly in dementia that the reasoning powers as well as other mental attributes fail.

c. The varied impulses to action which operate in health are all liable to affection in mental disease. The strong man becomes vacillating, the weak and timid grows obstinate and resolute. It is indeed curious to

observe how, in some cases, the patient seems to lose all power of will, how he apparently loses all capacity not only for directing his thoughts, but to decide for himself whether or not he shall perform even the most trivial action; while, in others, he seems impelled even against his reason by a stubborn and unbending determination to perform some malicious or wicked deed, or to carry out some absurd design. Careful examination and inquiry will probably show in every case that there is a more or less manifest failure of that higher element of the will, in virtue of which we fix attention upon ideas and trains of thought, compare, analyse, and force them into due relation, and by means of which we control and direct the various impulses to action determined by our perceptions and ideas, and by the moods and passions which alternately sway the mind. It is largely owing to the former of these conditions that the victim of hallucinations of these senses ends by accepting his hallucinations as facts and that so-called 'insane' ideas become fundamental beliefs. And it is due in great measure to the second of these conditions that the patient, yielding to the uncontrolled impulses of the moment, performs acts which in a healthy frame of mind his reason would have restrained him from. It often happens that, compelled by impulses, against which haply they may have striven with all their might, patients, not apparently otherwise insane, commit thefts, perform indecent acts in public, set fire to hay-stacks or houses, or give themselves up to bouts of drinking. At the same time it is important to recollect that apparently impulsive insane actions are not necessarily or even principally due to instinctive or moral causes. In a large number of cases, and in many instances too where it is wholly unsuspected, the patient acts under the influence of some delusion: he is ordered by some peremptory voice, by Christ himself, to help himself to his neighbour's breakfast or to pick his pocket; he puts his hand into the fire and reduces it to a cinder, in the belief that fire has no influence over him; he refuses food, because he belongs to the immortals, and does not need it, or because he imagines it is poisoned; he remains motionless for fear that being made of glass he shall be broken in pieces, or because a false step or even a change of position shall reveal him to those who are seeking his life or cast him headlong down a precipice.

*d. The destructive tendencies*, already referred to in the last paragraph, which are common in madness, but chiefly in that variety of it known as melancholia, form an exceedingly interesting study. They may be suicidal, homicidal, or directed against the lower animals or inanimate objects. And they arise in different ways. In some cases persons unaffected with hallucinations or delusions become the subjects of a more or less uncontrollable impulse to destroy themselves, to kill infants entrusted to their care, or to smash, burn, or otherwise destroy. Thus, even young children commit suicide from simple disgust of life, or on account of some petty disappointment or annoyance, or brutally murder their playmates for no obvious cause; and many such patients (more especially adults) actually recognise their miserable condition and bewail it, strive for a

time, at any rate, more or less successfully against their impulses, and even seek the restraint of a madhouse. In other cases, as for example in the course of epilepsy, patients are suddenly urged by some blind ungovernable rage to commit the grossest outrages, to mutilate, to murder, or it may be to destroy themselves. In other cases, the impulse to suicide or murder is the almost necessary result of the long-continued mental misery from which the patient suffers; under the influence of his profound depression, perceiving no other possibility of escape from sorrow, he destroys himself; or, in order to save them from a wretched future, or to send them to a better world, he takes the lives of those who are dearest to him. But very frequently the determining cause of the patient's action is some hallucination or delusion which dominates his mind; he kills himself because some voice he dares not disobey tells him to do it; he makes murderous attacks either to defend himself from those whom he supposes to be working him mischief, or to destroy the arch-fiend whom he believes to be present in human guise, or to save his friends from impending peril. It is important to observe, however, that murder or suicide by the insane is not always due to any *destructive* desire or impulse; but that occasionally, for example, a madman will kill himself in the attempt to prove his immortality, or his child in the full belief that he is Christ and will rise the third day. Among destructive impulses must, of course, be included those which impel patients to tear up their clothes and bedclothes, and especially those which incite them to the setting fire to hay-stacks, houses, and the like. It must not be forgotten that all melancholic patients, however inoffensive they may seem to be habitually, are liable in a greater or less degree to sudden impulses to kill or destroy.

3. *Disorders of movement.*—In the remarks just made the performance of combined actions in obedience to the dictates of emotional impulses or of the will were alone under consideration. Under the present heading it is intended simply to call attention to the modes in which muscular actions are executed in madness—to the defects or modifications of movements which may be present. It is probably rare to observe entire healthiness of action in those who are insane. In most cases the expression of the features or the movements of the body reveal to the practised eye the patient's mental condition. The wandering look of one, the sullen or suspicious aspect of another, the self-satisfied air of a third, are severally in full accordance with the prevailing emotional condition; and a similar conformity may be observed between the restlessness of movement, the inertness of manner, the obstinate immobility, which are frequently met with, and the patient's state of mind. But other muscular phenomena besides these are generally present. In some cases the muscles are rigid, in some relaxed. In some there is apparently excess (temporary, no doubt) of muscular strength, in more there is actual loss of power. Occasionally a condition of catalepsy is present. Further, local paralyses and spasms, such as occur under other circumstances, are not uncommon here; among which may be included hemiplegia, paralysis

of certain nerves connected with the head and neck and face, epileptic convulsions, convulsive movements of particular parts, chorea-like affections, rhythmical actions, difficulties of articulation, and nystagmus. As regards the special phenomena of 'general paralysis of the insane,' we shall reserve our observations until we come to the consideration of that disease.

4. In most, if not in all cases of insanity, the several disorders which have just been discussed separately, and may exist alone, become combined in a greater or less degree, and concur in the development of the special insane mental phenomena which each patient presents; and they act and react on one another in such a way that it becomes extremely difficult and often impossible to estimate their several influences upon the patient's thoughts and actions. This difficulty is especially great in the case of dementia, where the perverted mental powers have undergone gradual deterioration, and the motives to action are mainly the satisfaction of the appetites, and the mere shreds of moral and intellectual attributes which survive the general mental wreck.

The remarkable resemblances which exist between dreaming and states of somnambulism, artificially induced, on the one hand, and insanity on the other, have long been observed. In dreaming our mental faculties are only partly annulled by sleep. Some are still wakeful, but wakeful in different degrees; and between these all sense of proportion is lost. Subordinate mental phenomena, fitfully or not at all controlled by the higher intellectual powers, attain unwonted importance. Ideas and hallucinations, ever varying and with little interconnection, but determined to some extent by sensory impressions, and by the thoughts and occupations which preceded sleep, crowd the mind, and are accepted by it as realities. There is a total loss of knowledge of our actual relations to the external world, including our relations to time and space. Memory fails to recall in orderly sequence the events of our past lives, even those which have just occurred; but it brings together confusedly fragments of previous experiences, sometimes fragments which had seemed to be utterly forgotten, and blends them into contemporaneous pictures. It even invents recollections; and passing thoughts are taken for personal reminiscences of what never occurred to us. The reasoning faculties specially fail. There is little or no power of comparing or analysing the pictures or ideas which present themselves to the mind; however absurd, however outrageous, however impossible they would appear to us if awake, they are accepted as a rule without question and as a matter of course by our sleeping minds; and even though at times we appear to ourselves to reason with acuteness and to argue with force and triumphantly, it is well known that almost always, if on waking our arguments can be recalled to mind, they prove to be disconnected, shallow, and even nonsensical. The moral feelings are also involved in sleep. Sentiments of joy, vanity, pride, and generally of exaltation, are by no means unfrequently excited; and on the other hand, cunning, hypocrisy, remorse, ungovernable fury, cowardice, and horror are common mental phases of the sleeping state.

Further, it may be remarked that at any rate some forms of insanity have a resemblance to dreaming, in the facts of the abeyance of the external senses and of their normal influence over the mind, and of the more or less complete severance between the mental phenomena and the responsive actions of the muscles.

In connection with this subject it is interesting to consider, that it is not uncommon for insane persons during convalescence or after recovery to speak of their past mental condition as though it had been a dream; that the outbreaks of temporary impulsive insanity which sometimes precede, sometimes replace, but more commonly follow, an attack of epilepsy, and which often impel the patient to deeds of purposeless violence, are apt to pass absolutely from the memory, as a dream often does; and, further, that if the dreamer were during his sleep to act in accordance with his delusions and impulses, as in his dream he believes he does—if the honest man were to pilfer, the virtuous man to commit rape, the loving father to disembowel his child and put it in the dust-bin, if he were to hold audible conversations with his interlocutors, and generally were visibly to play his part in the fantastic and unreal world in which he seems to live—there would be little to distinguish between the condition of the sleeper and that of the lunatic, except perhaps that the lunatic is more or less alive to all that is going on round about him, and that the facts of the external world and his relations to them (it may be falsely seen and falsely interpreted) are mingled with his insane moods, his insane ideas, and his other insane subjective phenomena.

B. *Special description*.—There are two fundamental divisions of insanity: the one characterised mainly by perversion or disease of the emotions or passions, the other characterised mainly by perversion or disease of the reasoning powers. The former is termed *affective insanity*, the latter *ideational* or *intellectual insanity*. It is not pretended that all lunatics can be placed in one or other of these categories, or, indeed, that affective insanity and ideational insanity ever exist wholly independently of one another; but it is a fact that in the great majority of cases insanity commences with some change in the feelings, some perversion of the moral qualities, some affection of the passions, which stamps itself on the features and demeanour and influences the conduct; and that it is only subsequently that delusions and other distinct evidences of intellectual disease manifest themselves. It is a fact too that the patient may never pass beyond the stage of affective insanity; and it may be repeated that moral perversion persists as perhaps the most important factor in the constitution of all cases even of ideational insanity.

Again, it is now generally acknowledged, as Guislain was the first to establish, that in by far the larger number of cases the earliest indications of insanity consist in a 'state of profound emotional perversion of a *depressing and sorrowful character*,' and that it is only at a later stage, if at all, that morbid feelings and passions of exaltation show themselves.

Although fully admitting the truth of the principles just enunciated, we shall not attempt, any more than other authors have done, to classify

the varieties of insanity according to one or other of them ; and while acknowledging most thoroughly that different forms of insanity pass into one another, and that many cases are met with which can only with a certain amount of violence be assigned to any particular division, we shall adopt, in the main, the system of classification which has been accepted—at any rate in principle—by most writers on the subject. Accordingly we shall arrange mental diseases under the following six heads :—

1. Melancholia, madness characterised by mental depression ;
2. Mania, madness characterised by mental exaltation ;
3. Monomania, or partial madness, generally attended with exaltation ;
4. Dementia, madness characterised especially by mental weakness ;
5. General paralysis of the insane ;
6. Idiocy, amentia, or congenital mental defect.

1. *Melancholia*.—The specific character, the fundamental phenomenon, of melancholia is the presence of a profound sense of painful depression—a feeling of oppression, anxiety, dejection, and gloom. This condition, indeed, as has already been stated, constitutes the early stage of most cases of insanity. It may come on without obvious cause, or it may supervene on some bodily illness, or on some mental perturbation or shock. For the most part its onset is gradual ; the patient feels unhappy, irritable, annoyed with himself and all about him ; he loses interest in what formerly gave him pleasure ; everything is a trouble or misery to him. The world is physically unchanged to him, and yet an altered relation between himself and it has arisen which he cannot understand and for which he cannot yet assign a cause. At first he most likely endeavours to conceal the wretchedness he feels ; but soon probably he either mopes, withdraws himself from observation, and neglects his business and his duties, or gives vent to his feelings in irritability of manner and tendency to quarrel, and perhaps displays malice or hatred towards those who should be, and were, dearest to him. The malady may not proceed beyond this point ; but in most cases hallucinations and delusions manifest themselves after a time—hallucinations and delusions which correspond closely in character with the patient's affective state. It was formerly believed, and is even now not unfrequently supposed, that the delusions of melancholia are the cause of the patient's mental gloom and misery ; but that is not the case. On the contrary, the special delusion or delusions which he manifests crystallise, so to speak, out of his large and vague feeling of depression. Seeking, it may be, for some explanation of his altered state, which probably no one, up to this time, appreciates and deplores more than he himself does, his mind dwells upon some special subject (determined, probably, by his former pursuits or inclinations, or by accidental circumstances), until at length it assumes a predominant influence over him, and becomes transformed into a delusion. This apparent revelation to him of the cause of his mental change is, oddly enough, not unfrequently attended with some diminution of his despondency ; and oddly, too—a circumstance tending to show that the delusion is not the real cause of his condition—the discovered cause

is often altogether trivial, and quite inadequate to explain the consequences supposed to flow from it, just as the intense horror or dread which attends nightmare is for the most part altogether disproportionate to the imaginary incidents which seem to cause it. The delusions of melancholia are of the most varied kind. In a large number of cases the patient believes that he has committed some inexpiable crime, that he has done murder, if not in deed in thought, that he is a thief, that he has been unchaste, that he has committed the unpardonable sin, that he is a disgrace to his family and to humanity, that he is forsaken of God, and doomed to eternal punishment. In other cases he harbours the delusion that some kind of possession or transformation has taken place in him : he is possessed by the devil or by a legion of devils, or he has been transformed into the evil one ; he has become a dog, a wolf, a toad ; he is made of glass ; he is a mass of corruption ; he exhales offensive odours, which render him an object of disgust ; he is a corpse, or his former self is dead, and that which passes for him is something or someone else. Or his delusions have special reference to other persons : he is an object of general suspicion ; everyone is making remarks about him, or pointing him out ; detectives are on the look-out for him ; spies are constantly dogging his footsteps ; his friends are untrue, or his wife unfaithful ; or dreadful calamities are threatening those who are dearest to him—calamities for which, probably, he is in some way or other answerable, but which he cannot prevent. Or he regards himself as the victim of some person, some power, or some conspiracy : he is being poisoned ; he is subjected to the influence of electricity ; his thoughts and actions are directed in some marvellous way by someone who owes him a grudge, or has acquired undue influence over him ; he is mesmerised or bewitched. It is almost needless to say that hallucinations and illusions are usually associated with the patient's delusions, and form an integral part of them. There is little doubt that the belief so common among melancholics, that they are being galvanised, is determined mainly by hallucinations or illusions of common sensation, and that the notion of being made of glass, of being slowly burnt, of being one of the lower animals, of harbouring inside them unholy or loathsome beings, is equally connected with some perversion of the cutaneous or visceral sensibility. The delusion that he is a corpse, that he is being poisoned, that he exhales a disgusting odour, may sometimes be referred to affections of the patient's sense of taste or smell. It is in this form of madness especially that the sufferer hears voices which whisper abominable words or sentiments, which revile and upbraid him, which utter calumnies against his friends, which tell him that he is damned, which incite him to acts of violence or crime. Hallucinations of sight also are common : the patient sees the enemies or fiends that are pursuing him, the judge and jury before whom he is being tried, portents in the heavens, death and destruction around him, hell yawning at his feet.

The aspect and demeanour of melancholic patients, though very various, are in accordance with their mental condition. The expression is, according to circumstances, irresolute, sad, suspicious, moody, or con-

centrated; the eyes are cast down, or fixed with an intense look of pain or horror. Generally the patient's movements are languid and feeble, and he remains, perhaps, all day long in one place, and even in one position. Sometimes, under these circumstances, his limbs become rigid, and his muscles may even assume a cataleptic condition; sometimes, on the other hand, they are flaccid. In many cases the patient is restless, constantly moving about, perhaps hovering around the keeper or the doctor, from whom, maybe, he vaguely hopes to obtain relief from his sufferings; or he takes long walks, and not unfrequently bursts out crying and wrings his hands in an agony of grief or despair. He bites his nails, plucks out his hair, rubs his skin into holes.

Sensibility is often affected in melancholia. There may be more or less general anæsthesia; or there may be uneasy sensations referred to the limbs or trunk, to the skin or internal organs. Especially, perhaps, the patient suffers from epigastric pain, abnormal feelings in the head and spine, and diminution of sexual desire.

The sleep of melancholics is usually disturbed. For the most part they sleep little, are troubled with painful dreams, and wake up unrefreshed. They are apt to believe erroneously that they do not sleep at all.

The gastro-intestinal functions generally suffer. There is almost always constipation. The appetite often fails: but sometimes, on the other hand, it is almost insatiable. The refusal to take food, so common in melancholia, does not usually depend on loss of appetite, but rather arises from the fear of being poisoned, the wish to commit suicide, obedience to some command, or some other delusion. Nutrition often suffers; the patient emaciates, his skin becomes harsh and dry, his face assumes a livid or cadaverous hue, which, with the attendant emaciation and modification of expression, imparts a premature aspect of age; his temperature becomes lowered, his pulse weak and often slow, and his extremities cold and livid.

The course of melancholia is for the most part chronic. In some instances the patient presents remissions, and much more rarely complete intermissions or lucid intervals of short duration. Occasionally the disease is *recurrent*, the attacks, which usually resemble one another accurately, being separated by irregular and comparatively long intervals of sanity. Again, cases are not unfrequently met with (the *folie circulaire* of Falret) in which insanity presents throughout its course a succession of alternate stages of melancholia and mania. Melancholia of low intensity may continue with little change for many years. It has already been pointed out that a melancholic stage precedes most maniacal outbreaks. But this is generally of short duration. Melancholia may leave behind more or less marked traces of mental weakness, and may end in dementia. It has been estimated that somewhat more than half the cases of melancholia get well ultimately, although of these a large proportion are liable to relapse; and that, of the remainder, some continue with little change of symptoms, others pass into mental weakness or dementia, and others die. If recovery takes place it is generally gradual,

and within six or twelve months from the time of seizure. Should the symptoms extend beyond this limit, recovery is almost hopeless. Death may be due to self-inflicted injuries, to starvation or its consequences, to phthisis or other tubercular affections which are extremely common in this form of insanity, and lastly to pneumonia, or other intercurrent visceral affections. It has been observed that diseases, more especially, perhaps, acute diseases, occurring in the course of melancholia, are apt to have an important influence over it ; sometimes they ameliorate, or even cure, the mental malady ; but in other cases, and probably quite as often, they aggravate it.

The above account of melancholia is general, and applies more or less accurately to the greater number of cases that come under observation. But there are several groups of cases which present special characteristics, and require, therefore, separate consideration.

*a. Hypochondriasis* is often not regarded as a form of insanity. But, as Griesinger observes, it is properly a *folie raisonnée mélancolique*, a form of melancholia in which there is mental depression, without necessary delusion or marked impairment of the reasoning powers, characterised especially by a sense of profound illness, and a tendency to exaggerate the feelings of illness, and to brood over them. Hypochondriacal patients, for the most part, but not necessarily, suffer from uneasiness, pain, or actual illness, and it is in connection with this mainly that their feelings of profound misery and gloomy forebodings arise. They dwell constantly on their real or supposed maladies ; they examine and discuss mentally every new phenomenon which presents itself ; they are always looking at the tongue or feeling the pulse, and on the watch for new symptoms ; not merely on altogether insufficient grounds, probably, do they argue themselves into the belief that they have certain internal diseases which must prove fatal, or render their lives utterly miserable, but they invent outrageous explanations of obscure groups of symptoms, such as that they have toads or serpents inside, or that their food coagulates within them and forms a solid mould of the stomach and bowels, or that they are devoid of these important organs ; they consult medical works and apply to themselves the horrors of which they read ; and their conversation for the most part is a wearisome iteration of their imaginary or exaggerated sufferings. They usually take little or no interest in other persons' affairs ; are selfish, querulous, and quarrelsome, weak, vacillating, and infirm of purpose ; they have an air of sadness or misery, and neglect the duties which devolve upon them. Not unfrequently new maladies arise and replace the old ones ; and they have a tendency to go from physician to physician in search of the relief or cure which does not come. Occasionally actual insane delusions arise, chiefly in connection with their predominant feelings of illness, and the patients become mad beyond all question ; and very commonly, although they reason correctly on all other subjects, their mental powers appear to be clouded and weak in regard to the supposed cause of their maladies. It is not often that hypochondriacs are impelled to murder or even to suicide. Hypochon-

driasis is most common in middle-aged and elderly men. As it is often associated with the presence of actual disease, it is always important to institute a careful examination of hypochondriacal patients. Recovery is not unusual under appropriate treatment.

*b. Melancholia with stupor, or melancholia attonita*, is a variety of melancholia which presents a superficial resemblance to dementia, was long confounded with it, and even now is sometimes difficult to distinguish from it. In this affection the patient's whole mind appears to be engrossed in one all-absorbing painful delusion; and, though his senses are open and convey to the sensorium all the impressions they receive, his preoccupied mind takes little or no cognisance of them, and his features and limbs remain alike motionless. The nature of the delusions from which the patient suffers differs of course in different cases; sometimes there is simply a vague sense of impending calamity, sometimes he stands on the brink of an abyss or in the midst of a conflagration, sometimes he has committed some great crime and awaits the verdict of the jury and the sentence of the judge, or the day of his damnation has come, and heaven and earth are passing away as a scroll. His expression is fixed, and it might even be imagined that he was insensible; but his face wears a look of intense horror, awe, grief, or anxiety. His limbs are motionless, occasionally flaccid, occasionally rigid, or plastic as in the cataleptic condition. He takes no notice of what is actually going on around him; he does not flinch from ordinary painful impressions, or from noises made close to his ears, or blows aimed at his eyes; but probably his pupils contract to light, and if a jugful of water be poured on him a sudden inspiration follows. He takes no food, or at any rate requires to be fed; he passes his evacuations without notice, and if not confined to bed needs to be put to bed and taken out of it, dressed and undressed, like a patient in a late stage of dementia. Melancholia with stupor may last for a few hours only, or for several days, weeks, or months. It sometimes comes on in the course of other forms of insanity, sometimes arises suddenly, especially after a severe mental shock, or in connection with epilepsy. Recovery from it is often sudden; and on recovering the patient is apt to express himself as if he had awakened from some frightful dream—indeed, there is a marked resemblance between this condition and nightmare.

*c. Melancholia with excitement*.—Melancholia occasionally puts on the trappings of mania. In this case the bodily activity is much greater than it is in ordinary cases of melancholia; the patient is excited, restless, rambles about, and wrings his hands, or performs other muscular movements; but withal his frame of mind and his delusions are less variable than they usually are in mania, and present, as is indicative of melancholia, a certain degree of monotony.

2. *Mania* is characterised specially by sentimental exaltation, intellectual vivacity and incoherence, and excited muscular action. It may break out suddenly, or come on in the course of certain acute febrile and other disorders. But much more commonly its onset is insidious. In

this case it is usually ushered in, as melancholia is, with depression ; and indeed, the beginnings of both forms of insanity are in the main identical. After the period of depression has lasted a longer or shorter time, the patient's condition gradually changes, he becomes restless, dissatisfied, wanders about, roams the streets or fields, or visits friends, with the vain hope of obtaining relief from his distressful feelings ; and then by insensible gradations his depression and discomfort cease, he becomes lively, loquacious, and boisterous, is readily excited to anger or laughter, is vivacious and varied in his thoughts and language, speaks in a loud tone, entertains an overweening opinion of his bodily and mental powers, and displays increased and incessant muscular activity. During the stage of mental depression he often feels ill, and complains of painful or uncomfortable sensations referred to different parts ; but as the true maniacal condition supervenes such feelings subside, and he seems to himself to be in the best of health.

The most remarkable features of mania are the disturbance of the affective functions which it presents, and the impulse to incessant activity which accompanies this disturbance. The patient's moods are for the most part moods of exaltation, and are not only different in different cases as regards both intensity and character, but are constantly varying in the same individual. Sometimes the patient is sad, ill-tempered, angry, suspicious, or ferocious ; more frequently, perhaps, he is gay, jovial, boisterous, or vain, proud, and arrogant ; or, again, he may be acquisitive, or lascivious, or dominated by other appetites. In accordance with these various moods or moral conditions, we observe some patients indulging in frivolous or harmless actions, such as dancing, singing, laughing, shouting ; some cursing and swearing, using obscene language, tearing and destroying whatever comes in their way, and committing violent and unprovoked assaults ; some collecting and accumulating all kinds of rubbish and filth or freely displaying their lascivious feelings and even masturbating openly and shamelessly, or eating garbage and even faecal matter, or giving themselves to drink. Some of these affective states, and the actions which result from them, are determined by bodily disorders, especially by conditions of the sexual organs ; and not unfrequently, at any rate in the earlier stages, the patient is apt to have some consciousness of his abnormal state, and will occasionally try to control or conceal it.

The intellectual characteristic of mania is not so much the existence of hallucinations and delusions, though these are usually if not always present, as the incessant tumultuous flow of ideas. In its slightest form this amounts to little more than an increased vivacity of thought, accompanied probably by an exaltation of the memory, which manifests itself by unusual brilliancy of conversation, readiness of retort or sarcasm, an aptitude to look at things in new lights, to see unsuspected resemblances, and hence to utter witty or humorous or poetical expressions and thoughts, a tendency to speak in rhyme, to discourse with unwonted fluency and eloquence, and to propound startling speculations and theories. In more advanced cases, or in severer forms of mania, this apparent intellectual

elevation runs into incoherence ; ideas, still more or less in accordance with the patient's affective condition, and still following one another rapidly, have now little or no connection with one another ; there may still be flashes of wit or sarcasm, still fragments of eloquence or of versification, still thoughts of exaltation, but they are determined largely by impressions made upon the senses, and pass from the patient's mind as soon as they are uttered or expressed.

Illusions, hallucinations, and delusions are all common in mania, and their presence largely influences the character of the patient's thoughts, and determines his speech and actions ; moreover, they themselves are in their origin intimately related to the feelings which are predominant in the mind. It is owing probably to illusions or hallucinations of the muscular sense that maniacs so often entertain the belief that they are endowed with superhuman strength ; that they can run, or fly, or play at cricket, or perform other athletic exercises with marvellous skill. And it is due in some degree to cognate causes that such patients write or recite incoherent nonsense which they regard as poems of surpassing beauty ; that they boast themselves to be mathematicians, or orators, or singers, such as the world has never before seen ; that they believe themselves to be in communication or correspondence with statesmen and emperors ; that they regard themselves as possessors of untold wealth, and even of the asylum in which they are incarcerated : and that they hold themselves to be Wellington or Napoleon, the Queen, the brother of Christ, or Christ himself, or, it may be, all three persons of the Trinity in one.

It is important, however, to observe that, in mania, the hallucinations and delusions which affect the patient are, like his ideas and moods, fleeting and various ; that individually they do not, as a rule, take any strong hold on the mind ; and that, in this respect, there is a marked contrast between mania and melancholia, and especially between mania and monomania.

Sleep is generally impaired in mania. It is often troubled, and, in many cases, sleeplessness may be continued without intermission for weeks or even months. A good night's rest, though in itself a favourable sign, often occurs without the slightest benefit to the mental condition of the patient.

The movements of maniacs are in many cases incessant. It is often held that maniacal patients are stronger than they were in health ; but this is for the most part incorrect. Nevertheless it is remarkable how they will sometimes, without any intermission by day or night, and apparently without fatigue, continue for many weeks to execute violent muscular movements.

Various sensory phenomena are apt to arise in the course of mania, such as headache, uneasiness at the chest, aches in the limbs, sensations of heat and cold, and the like. Anæsthesia, too, is sometimes observed. The appetite is often enormously increased ; but in some cases the desire for food is wholly absent. Sexual feelings are generally increased, and

more especially in females ; and reveal themselves by looks and gestures, obscene language, and the like. The menses are generally irregular or absent. There is nothing special to observe about the circulation except that it is often weak, and the pulse somewhat quicker than usual. The face is apt to be congested and the eyes bloodshot ; but, on the other hand, the hue of the skin is not unfrequently sallow and even cyanotic. Notwithstanding the patient's probably enormous appetite, he usually becomes thin and wrinkled, and looks older than he is. The bowels are apt to be irregular, and especially to be constipated. The temperature of the body is for the most part normal. Occasionally, however, it rises a little, in connection with bodily illness, and especially in those cases in which the patient has little sleep and passes into a typhoid state. Occasionally, also, there is local increase of temperature in the head.

The course of mania varies in different cases. In some instances it is uniformly progressive ; but much more commonly it is attended with alternate exacerbations and remissions—the latter being sometimes complete. Complete intermissions sometimes occur periodically. Exacerbations are likely to supervene at the menstrual periods ; but in a large number of cases the variations in the condition of the patient take place, so far as can be ascertained, without obvious cause. We have already referred to the periodical alternations between mania and melancholia, to which condition the name of *folie circulaire* has been given. Maniacal outbreaks may vary in duration between a few hours and several months ; but in most cases, and generally when the attacks are of long standing, they are attended with remissions, and may thus be continued for many years. Recovery from mania is sometimes sudden ; but more commonly it takes place gradually. Occasionally its cessation is connected with the super-vention of some bodily disease, such as diarrhœa or fever. Recovery generally takes place, if at all, within a year ; but is by no means hopeless even up to the end of the second year. After this it is rare ; yet cases are occasionally met with in which it has been delayed until after the sixth or seventh year. The terminations of mania, other than the termination in recovery, are, first in chronic mania, second in dementia, and third in death. The last event may be due to simple exhaustion, to the supervention of pneumonia, pleurisy, cerebral congestion, or other diseases, or to injuries accidentally inflicted. It may be added that patients who have once had an attack of mania are very apt to have relapses ; and, again, that when maniacal patients are suffering from tubercular or other intercurrent diseases, these, however acute their progress, appear to cause but little suffering, and may therefore easily be overlooked.

Mania, like melancholia, presents many sub-varieties, characterised by special peculiarities. We shall refer briefly to a few of them. *Delirium tremens*, which has been elsewhere described, is manifestly a form of acute mania. The *acute delirium* of French writers is mania, characterised by suddenness of outbreak ; by 'furious delirium with incessant incoherent chattering, but with the dominant expression of anxiety ;' by 'vertigo,

awkward trembling movements as if the patient were intoxicated ;' by sleeplessness, paleness of countenance, dry tongue, and rapid exhaustion. The disease is often attended with fever, lasts from a few days to several weeks, and frequently terminates fatally by collapse. *Recurrent or periodic mania* is that form of the disease in which the attacks of mania are separated by considerable intervals of sanity. It is remarkable that here, as in the corresponding variety of melancholia, the successive attacks are almost exact repetitions of those that went before. To the *folie circulaire* of the French writers we may again call attention. It resembles the last variety of mania, excepting in the fact that the attacks of madness present alternate stages of mental depression and mental exaltation. *Mania transitoria* is the name given to acute outbreaks, lasting probably for a few hours only. They are sometimes epileptic, sometimes hysterical, sometimes the result of drink, and may arise under various other conditions. Lastly, the so-called *mania sine delirio*, or *folie raisonnante*, must be regarded as one of the varieties, and by no means an unimportant variety, of mania. It is the condition in which the patient presents affective disturbances with corresponding movements or motor impulses ; but in which there is an absence of delusions and probably of hallucinations. It corresponds to the early stage of many cases of ordinary mania, and it may persist without going on to delusive insanity for an indefinite period. In such cases the patient presents some marked change in his moral nature : he becomes light-hearted, volatile, vain, arrogant, quarrelsome ; he neglects his business, or buys and sells or speculates wildly ; he devotes himself to pleasures ; he becomes acquisitive, perhaps steals : he talks and acts obscenely, and forms immoral connections ; he neglects or ill-uses his wife and children ; he takes to drinking ; he acquires expansive religious notions ; he entertains an exalted view of himself—his mental capacity, his personal appearance, and all that belongs to him. These, or such-like, are the perversions of mind or conduct which he displays, and which are all the more striking that they represent gross exaggerations of his natural characteristics, or are in absolute contradiction to them. Patients thus affected are capable of reasoning, and will probably, if interrogated, assign plausible grounds for their conduct, or invent ready excuses, and will perhaps display shame on the detection of their misdeeds. Although they are for the most part free from hallucinations or delusions, such phenomena are apt to supervene more or less suddenly, and in connection with these, or from other causes, they are always liable to sudden outbreaks of maniacal fury. This condition may end after a short time in recovery ; it may persist for a length of time with little obvious change ; it may pass into mania or monomania, or it may result in dementia.

3. *Monomania* is the term used to designate a form of insanity, specially related to mania, in which the patient, with exalted notions of his own importance, entertains fixed delusions which dominate his thoughts and conduct. It differs from melancholia in the absence of the profound and persistent depression which characterises that condition ; and from mania in the absence of that wealth of incoherent ideas, and of that restlessness

and vivacity of movement which belong to mania, and in the existence in their place of persistent delusions with the power of reasoning and of forming and carrying out enterprises or plans of action. Monomania may take its origin in mania or melancholia ; or it may come on independently, in which case it is usually preceded, as other forms of insanity are, by a stage of melancholy. Here, as in other cases, there is affection of both the moral and the intellectual side of the mind. Monomaniacs have usually an overweening opinion of their own importance ; they are self-satisfied, vain, haughty, arrogant. One is affable, polite, condescending in his demeanour. Another struts about with an air of insufferable pride, and treats those about him with lofty disdain. Some, especially females, are fond of dress, and deck themselves out fantastically or even show remarkable taste. A few, on the other hand, engrossed in other matters, are slovenly and dirty in their attire and habits. Sometimes they express themselves habitually in pompous or theatrical language. Sometimes they present an air of perfect calm, their conversation and conduct indicating a supreme tranquil joy. The delusions under which such patients labour are necessarily various, though for the most part of an exalted character. In some cases they look upon themselves as great discoverers : they have solved the problem of perpetual motion, have squared the circle, or have invented machines capable of doing impossibilities. In some cases they regard themselves as having extraordinary knowledge, genius, or power : they are wiser than any who have gone before ; they are distinguished generals or statesmen, or royal personages, or great poets ; and they even assume themselves to be specific historical or Biblical characters. Not unfrequently they believe themselves to be benefactors of mankind ; they have revealed conspiracies, and their praises are on everybody's tongue ; or they are apostles or prophets. Occasionally, however, their delusions are of a lower grade : they are objects of suspicion ; they are being constantly tracked ; and people sneeze or cough or make signs which have some mysterious relation to them. Hallucinations and illusions are often associated with the delusions of these patients, and react upon their mental condition. We have referred to the fact that monomanics retain for the most part considerable power of reasoning. In many cases they discuss matters unconnected with their special delusions with perfect intelligence ; and even in relation to their delusions they can usually adduce plausible and even striking arguments ; but that their mental powers are weakened is undoubted. Firm in their beliefs, they are apt to meet objections with a flat denial or a simple assertion of their claims, and generally ignore their opponent's arguments. They entertain, in fact, a fundamental belief which is beyond controversy. Monomaniacs, especially in asylums, are often quiet and harmless in their behaviour ; but when thwarted or contradicted, and occasionally even when unprovoked, they are apt to become violent and dangerous, and to exhibit maniacal and ungovernable fury.

Monomania seldom ends in recovery, and especially rarely if it has existed over six months. It often becomes chronic, and continues with

little change for many years. It generally, however, passes sooner or later into dementia. The bodily health is usually good, unless the monomania be of a hypochondriacal character.

4. *Dementia*.—By this is meant, not as in the forms of insanity hitherto considered, a qualitative change or perversion of the mind, but its deterioration or decay. It is the natural termination of all incurable cases of melancholia, mania, and monomania; it commonly supervenes sooner or later in various forms of cerebral disease, such as epilepsy, sanguineous apoplexy, embolic softening, disseminated sclerosis, and tumours; and it is apt to come on after long indulgence in drink or masturbation, and as one of the accompaniments of old age. Further it occasionally follows, as a primary and acute disease, certain of the acute febrile disorders, and severe mental or bodily shocks. It is interesting, as Griesinger remarks, that the dementia of old age is not unfrequently preceded by a stage of mild maniacal excitement. Perhaps the most remarkable characteristic of dementia, and that by which it contrasts strikingly with the acuter forms of insanity, is the profound loss which its victims manifest of those moral attributes and sentiments which form so important a part of the healthy mental condition, and which by their perversion or intensification constitute the very basis of mania and melancholia. The patient is no longer impelled by passion or by feeling; his acts are not determined by any persistent mood; he is incapable of intense hate or deep love; he manifests no interest in those about him, and the loss of friends or relatives, even of those who were dearest to him, affects him little or not at all. It is not meant that there is a total absence of emotions, but they are superficial, they come and go, they exercise no lasting influence, they do not determine the patient's course of action, but they spring momentarily from the impressions made on the senses or the ideas that come to the front. Impairment of the intellect waits upon the moral abeyance. There is always feebleness of the mental powers: memory fails; the patient probably forgets everything that has occurred during the day, and most that has happened to him during his illness; but he still calls to mind in a disorderly manner the events of his former life, and the delirious ideas that thronged his mind during his melancholic or maniacal state. He cannot reason; he is incapable of abstract thought. For the most part the loss of the reasoning power is obvious; the patient's thoughts and words are incoherent; he harps upon certain formulæ, and does not care or is unable to join in continuous conversation; and it is a remarkable fact, universally recognised of demented persons, that they are incapable of combining together to form plots, and that large numbers of them collected in a ward may be led and managed by one or two attendants like a flock of sheep. In association with the loss of memory and of the reasoning faculty, we find that delirious ideas, hallucinations, and illusions abound. Delusions, however, are rarely developed afresh. Those which are present remain over for the most part from the active stage of madness which preceded dementia; and they now probably form the centre, so to speak, of the patient's mental operations. They form funda-

mental facts, their reality is indisputable, and the patient's remnant of thought revolves about them, and clings, as it were, to them for support. The existence of hallucinations is shown by the frequency with which demented patients see absent persons and things and visions, and hear voices with which they probably converse audibly. The presence of illusions is manifested by the frequency with which they take persons about them for those who are absent or dead ; take pieces of glass and stone for precious stones or gold ; and regard old broken jugs and articles of furniture as their children who died long ago. Many of the strange occupations which demented patients delight in are indicative of the condition here adverted to. Thus, one, as Dr. Maudsley says, 'whose singular movements seem unaccountable, is busy spinning threads out of sunbeams,' while another 'continues the most violent movement of his arms in order to prevent the motion of the universe or of his own blood from coming to a stand,' and yet another turns about and performs strange antics under the belief that he is absorbing the verdure of the surrounding trees, with the object of utilising it in some mysterious way.

The actions of demented patients present remarkable variety, although showing considerable uniformity in the same individual. In some cases they are restless, in constant movement, incessantly chattering, making incoherent but occasionally pertinent remarks upon persons and things, yet having relation to their delusions ; in some they are perpetually making collections of stones, rags, feathers, and other rubbish, in the apparent belief that they are accumulating treasures of great value, or they appropriate their neighbour's food and other articles of property ; in some cases they mope in corners ; in some they pace incessantly backwards and forwards like a caged lion ; in some they adorn themselves fantastically ; in some they sit rocking themselves on a bench all day long. In connection with this subject it may be observed that some patients are lascivious in their conduct, and commit masturbation openly ; that, although there is no dominant feeling which guides their conduct, some are apt to smile and laugh, some to cry, some to break out suddenly in fits of violent passion, and some are mischievous or malicious in their general behaviour. Sooner or later they tend to become dirty in their habits and to pass their evacuations without restraint.

Patients suffering from dementia for the most part enjoy good bodily health, sleep well, have good appetites, and often become fat. But they have a vacant expression and a look of old age. As regards the duration and termination of the disease, it may be stated that imbeciles and demented persons usually live for many years, remaining at a certain level of intelligence, or very slowly becoming more and more childish and stupid ; that they rarely, if ever, get well ; and that death is due either to pneumonia, pleurisy, tuberculosis, or other intercurrent disorders, or to attacks of congestive or sanguineous apoplexy or to other brain affections. When the disease is primary and acute, however, recovery is not uncommon.

Dementia varies in degree and character. In one form of it, especially

as it is occasionally observed after apparent convalescence from an attack of acute mania, the patient becomes so far restored to his normal state that he is able to conduct his business and to perform the ordinary duties of life ; but his sensibilities are blunted, and he has lost all interest in and capacity for those pursuits and enjoyments which are the evidences and results of culture. He has lost all the freshness and spontaneity, all the higher and holier impulses, all the ideas and sentiments, that rendered him interesting and sociable ; and is content to pass his life automaton-like within the limits of a contracted sphere of thought and action. He is physically the same man that he formerly was, and he may seem perhaps to reason as acutely as ever ; he may even appear mentally healthy to those who see him for the first time ; but essentially and to his friends there is a profound change.

The greater number of permanent residents in asylums are persons whose dementia follows on mania, melancholia, or monomania, and in whom the delusions or insane ideas of their former condition still survive. They have lost the deep emotions which affected them then ; their mental powers have decayed ; but amid the general wreck of mind their delusions retain a more or less powerful hold upon them, and associated with hallucinations constitute the prominent parts of their mind and determine their actions. It is such patients that one sees performing all kinds of strange antics : polishing the floor with their saliva, taking the altitude of the absent sun with closed eye, directing magnetic currents, adorning themselves with fantastic ornaments, collecting rags and sticks, sitting perpetually dumb because they are God the Father, who speaks only through his Son, remaining fixed in one position because they are made of glass or wood, or believing that they contain strange monsters in their interior.

In another group of cases there is a still greater loss of the mental faculties. But for the fragments of delusions and ideas that, so to speak, play upon its surface, the mind is a blank. The memory is almost in abeyance ; they forget everything of the recent past, and most of what happened in their previous lives ; often they have lost all idea of their own identity, and have absolutely forgotten their own names. Objects about them make the usual impressions on the organs of sense ; but the impressions are scarcely, if at all, taken cognisance of by the mind. There is often more or less insensibility to pain. No new ideas are developed. All capacity for real sensibility or passion is of course absent ; but the patient nevertheless is apt either to present a uniformly joyous aspect, or he is disposed to cry, to show malice, or to be mischievous. Such patients are generally in constant movement, restless, and frequently pass a large portion of their time in chattering, laughing, or singing. Not unfrequently there are evidences of paralytic weakness of the limbs.

In yet another group of cases, and this constitutes the last stage of dementia, the patient's intellect is almost entirely annulled ; and his life is mainly vegetative. He takes no notice of what is going on about him, or of what happens to his own person ; fitfully perhaps he utters a few

sounds, it may be a few words, and gleams of emotion play across his vacant and meaningless features; he performs a few monotonous movements, or remains in one posture hour after hour, or if set walking continues to walk until his progress is arrested by force; he requires to be fed, to be dressed and undressed, to be put to bed and taken out of it, and to have all his wants attended to like a baby. Nutrition in this as in the other cases may remain unimpaired.

5. *General paralysis*.—This is a well-marked form of insanity, formerly confounded with mania, but clearly distinguished from it in the first instance by MM. Bayle and Calmeil, and now universally recognised as a specific disease. It differs from other forms of insanity anatomically in the fact that the symptoms depend directly on chronic inflammation of the grey surface of the brain, and clinically in the association with mental alienation of progressive paralysis of all the voluntary muscles.

General paralysis occurs much more frequently in men than in women. It is rarely if ever met with in persons under 20; and most commonly makes its appearance between the ages of 35 and 45. Its causes are various and often obscure. One of the most important is long-continued alcoholic intemperance. It is also attributed to venereal excesses, overwork, anxiety, mental shock, and physical injuries.

It usually commences with a prodromal period of uncertain duration, but which may last for several months, in which, as in the early periods of other forms of insanity, the moral or affective nature of the patient becomes more or less profoundly modified. He becomes restless and irritable, and disposed to take offence and be violent; he makes a show, may be, of still attending to his duties, but he gives himself up to debauchery, he lies, he speculates, he cheats or steals, and becomes a cause of deep anxiety to his friends.

Sooner or later the actual invasion of the disease takes place. This, according to M. Falret, may show itself in four different ways, in two of which the physical symptoms predominate, in two the psychological:—

a. In the *congestive variety*, the patient is suddenly attacked with an epileptic or apoplectic fit, which differs in nothing from the similar seizures which attend so many chronic affections of the brain. From this after a few hours or a few days he recovers, when it is probably observed that he presents maniacal excitement with grandiose delirium, or that there is some little impairment of memory and intellect, together with slight difficulty of speech and trembling of the lips. Not unfrequently there is progressive improvement in the patient's condition until another fit leads to aggravation of his symptoms. Occasionally the initial congestive attack shows itself, not in an actual fit, but in an outbreak of mania attended with hallucinations and delirious ideas.

b. In the *paralytic variety*, symptoms of paralysis precede all others, and probably attain a high degree of development before the obvious indications of mental alienation declare themselves. The patient under such circumstances himself observes that he is gradually losing muscular power, and that he cannot take the amount of exercise, or do the amount

of work that he formerly could do. He observes that his legs tremble, and that he has difficulty in ascending a hill or going upstairs; that his arms and hands are tremulous, and that he cannot write or perform other manual operations with his former dexterity; and further that his lips tremble when he speaks, and that his enunciation is imperfect. The paralytic phenomena gradually increase upon him; and ere long—it may be after a few weeks or a few months—the symptoms of cerebral excitement or alienation, which may have been gradually and imperceptibly creeping on even from the beginning, become clearly developed. The paralysis presents very striking features. It is generally first observable in the lips and tongue, and then extends with more or less uniformity of progress until it involves all the voluntary muscles. It is characterised by the association of tremulous movements (developed only when the patient exercises his muscles) with loss of power. The lips tremble at the moment of attempted utterance. So soon as the patient endeavours to open them a little hesitation or hitch in their movement, or distinct trembling, as though the patient were about to sob, may be observed. This appearance is generally regarded as of fatal omen. The tremor varies in degree, and may involve other parts besides the lips. Sometimes, indeed, the whole face, and even the orbiculares palpebrarum are thrown into muscular ripples when the patient speaks; and the jaws themselves may chatter as in the cold stage of an ague fit. The tongue trembles similarly when protruded. The effect of these movements on speech is remarkable. In some cases the patient simply hesitates a little; in some he slurs his words, or drawls them, or utters them in a monotone, or speaks as though he were scanning. Sometimes his speech is so tremulous that it can scarcely be understood; sometimes the preliminary movements of his lips and tongue are so prolonged and violent that he finds it impossible to get his words out. Not unfrequently he stammers or blunders in the use of words. The difficulty of speech is usually greatest when he is being watched or when he is nervous. The legs and arms are for the most part affected simultaneously; but sometimes the arms suffer earlier than the legs, and conversely; and occasionally the paralysis commences in the hemiplegic form. No doubt the loss of power is generally observed earliest in the legs; they become weak and tremble in use; the patient has difficulty in walking; he cannot readily rise from his seat; he walks bent forward with his legs apart, and takes short quick steps, and often has a tendency to run; he is easily thrown off his balance, and especially has a tendency to totter when suddenly checked in his onward progress, or made to turn. The arms also get weak and tremulous; and consequently the handwriting becomes shaky; and the patient soon has to give up writing, and any other manual labour, especially such labour as requires delicacy of touch—engraving, painting, playing musical instruments, and the like. The paralytic symptoms are not altogether unlike those which attend disseminated sclerosis; and occasionally the affection of the legs is that of ordinary locomotor ataxy, including loss of patellar reflex. Among the paralytic symptoms

must be included inequality in the pupils, and loss of action of the irides under the influence of light. Generally some degree of impairment of sensibility accompanies the motor paralysis.

c. The *expansive* variety, which commences with exaltation of mind and delirious ideas of an expansive kind, is the commonest variety of general paralysis. In this, paralysis comes on some little time after the insane symptoms have existed; and it may remain doubtful for a time whether or not the case is really one of the disease under consideration. The prodromal symptoms, which are mainly those of so-called 'moral insanity,' gradually undergo further development. Patients, who have hitherto been in a capricious frame of mind that has excited the uneasiness of their friends, become more restless, more excitable, more violent and wayward than they were. They talk, write, compose incessantly, and are constantly entertaining new projects. But at the same time there is a manifest failure of memory, especially in relation to things which have just happened. Their bodily activity is for the most part remarkable; they are always on the move, sometimes actively engaged in trivial matters, sometimes restlessly hurrying about from place to place, sometimes going on journeys and disappearing for a time without giving any intimation to those about them as to their proceedings. They are apt to do all kinds of outrageous things, to indulge in venereal excesses, to give themselves up to drinking, to steal, to undress in public places, to come to a dinner-party in dressing-gown and slippers, to spend money extravagantly, and to make valuable presents to persons who have no claim upon them, to speculate wildly, and to manifest alternately boisterous gaiety, reckless audacity, and sudden anger. Up to this point there may have been no true maniacal delirium. But ere long the grandiose notions and delusions which are so characteristic of this affection manifest themselves. These usually have relation to money and wealth. The patient, who perhaps is in receipt of a small precarious income, at first believes that his income is assured to him and double or treble what it really is; and by rapid strides he assumes that he is worth thousands, millions, millions of millions, that all the gold in the world is his. Or he enters upon imaginary speculations, buys up all the railways in England, all the railways in the world, and bestows salaries of hundreds of thousands a year on any casual acquaintance. Or he has a house of gold, surrounded by trees of gold and precious stones; he has extensive possessions, a county, a country, the whole universe. In connection with the idea of wealth arise ideas of glory, honour, and power. Such patients become distinguished soldiers, generals, emperors; they are great statesmen, poets, or philosophers; they are brothers of Christ, Christ himself, or the Almighty; they are hundreds of feet high; their strength is enormous; they can create giants and worlds; they can cure the sick and raise the dead. Their notions, too, are often fantastic as well as exalted; they have several rows of natural gold teeth; they have an unfailing growth of hair, which they can spin out of their heads as silkworms spin silk from their tails; they live on minced whales, stuffed elephants, and ostrich's eggs. The delirious fancies of general

paralytic patients are always associated with more or less dementia. Their delusions are not systematised ; and their actions are not necessarily in conformity with their delusions ; moreover, their delusions are variable, and are mingled in the most grotesque way with the circumstances of their daily life. Thus the man who believes that he is worth millions, and is ready to bestow thousands, will gladly accept a few shillings, will talk reasonably about his daily earnings, will beg piteously for a little tobacco. He who believes himself to be Christ will talk perhaps rationally on his private affairs, and be ready, if such has been his occupation, to polish your boots or sweep your chimney. The patient who is an emperor or king will tell you that his wife is a washerwoman and his children attend a charity school.

The characteristic paralytic phenomena always appear sooner or later in this case—generally as soon as distinct delusions manifest themselves—and rapidly progress from bad to worse.

d. The *melancholic variety* is rarer than the last, and in striking contrast with it. In this the patient is low-spirited and miserable ; he thinks he is ruined or dishonoured, he has committed unpardonable crimes, he is doomed to death, or to eternal punishment. His condition, indeed, is much like that of an ordinary melancholic patient, excepting that here, as in the last case, the symptoms are more variable, the delusions are less persistent, and occasional gleams of high spirits or grandiose delirium flash across his mind and reveal themselves in his aspect and behaviour. Occasionally the depression of spirits assumes a hypochondriacal character : the patient has uncomfortable feelings within him which become connected with some fantastic belief, such as that he has no inside, that he can neither swallow, defæcate, nor pass water, and so on. This melancholic condition may last throughout the whole period of the patient's illness ; or it may be replaced, sooner or later, by the ordinary form of exalted delusions. When it persists, it generally implies that the patient's illness is of a specially grave character, and that it will terminate rapidly in death—a result which is often accelerated by his refusal to take food, by malnutrition, and by the appearance of bed-sores. In this case, as in the last, the symptoms of paralysis more or less speedily complicate the patient's malady and stamp its real nature.

It must not be forgotten that, however the disease begins, sooner or later, if not from the very first, mental alienation and muscular paralysis become associated, and thenceforward run their downward course together. Nor must it be forgotten that, although cases are frequently met with in which the mental phenomena precede the symptoms referrible to the muscular system, and cases are occasionally met with in which muscular weakness appears to forestall insanity, in a very large proportion of cases the commencement of the two conditions is simultaneous.

When the disease is fully established, the special traces of the several varieties of origin are, for the most part, lost ; the paralysis has become considerable, and the mind, though still presenting delirious conceptions

of an exalted or, more rarely, of a depressed character, has sunk deeper into incoherence and dementia. The tremor of the lips and tongue, and the paralysis of the muscles of mastication and deglutition have advanced, so that the patient has great defect of articulation, perhaps cannot articulate, and has difficulty in chewing and swallowing; he probably cannot, without assistance, get upstairs or into his bed; he walks with difficulty across his room; he has lost the power of dressing himself, and even, may be, of carrying food to his mouth. There is impairment of co-ordination as well as weakness. Sometimes his muscles become contracted. His mental condition is that of dementia; he has lost nearly all notion of time, space, and locality; he has almost or entirely forgotten his father, mother, wife, and nearest relations; he shuffles about listlessly; he undresses himself at unsuitable times and places; he gets into his neighbour's bed, and appropriates his neighbour's food; he collects all kinds of rubbish. He is generally quiet and manageable, but occasionally presents sudden outbreaks of maniacal violence; and his mind is still, in a greater or less degree, the seat of delusions relating to riches and grandeur, or more rarely of such as are of a sad or painful nature.

In the last stage of general paralysis the patient has lost the power of locomotion, and is confined to bed or to a chair; the power of speech is annulled; he can no longer feed himself; he passes his evacuations incontinently into his bed or trousers; and his mind is sunk into the lowest depths of dementia; he knows no one, probably gives no indication of his wants, and passes his time in fumbling with his fingers, pulling to pieces his clothes or bed-linen, and uttering from time to time incoherent noises or cries.

There are two or three points in connection with the history of general paralysis which must not be omitted from our description. As regards the sensory organs, we have already pointed out that even early in the disease there is usually manifest impairment of common sensation. This anæsthesia becomes more pronounced as the malady progresses, until at length the patient takes no notice when he is pinched, pricked, or otherwise injured. It is curious, however, that he occasionally suffers from paroxysms of extreme hyperæsthesia. The other organs of sense for the most part remain unaffected; but smell and taste occasionally diminish in acuteness or become lost. The digestive organs usually act well; the appetite is unimpaired, and often sooner or later becomes ravenous; at this time, too, the patient crams his food into his mouth, and swallows it with little attempt at mastication. As a consequence, general paralytics are usually well-nourished and even become fat. In the last stage, however, emaciation may take place, bed-sores form, and diarrhœa, pneumonia, or tuberculosis supervene. Grinding of the teeth, convulsive actions of groups of muscles, and the copious exudation of sebaceous matter over the skin, are characteristic phenomena.

The progress of general paralysis is for the most part uniformly from bad to worse, and the patient, as a rule, dies within three years of the first accession of symptoms. But remissions are not rare, and occasionally

the disease becomes arrested in its progress. A few cases of recovery have been recorded.

The causes of death are various. In some cases, the patient dies of simple exhaustion, accelerated by bed-sores and other complications. In some cases, his death is due to asphyxia, resulting from the impaction of a bolus of food at the top of the larynx. The most interesting causes of death, however, are the apoplectiform seizures to which such patients are always liable. These are identical with those which occasionally usher in the disease. They occur at any period of its course, but more especially towards its termination, and recur from time to time. They invariably aggravate the patient's condition. They are ushered in with excitement and elevation of temperature; by which occurrences their advent may often be predicted. Their symptoms are, coma coming on sometimes suddenly, sometimes gradually, not infrequently convulsions or hemiplegia, and elevation of temperature to  $103^{\circ}$ ,  $104^{\circ}$ , or more. The attacks are not unlike those due to uræmic poisoning, and correspond pretty accurately to what was formerly called serous apoplexy.

6. *Idiocy* is a form of mental weakness which dates from birth, or comes on shortly after birth, at any rate before the mental faculties have reached their full development. It differs, therefore, from dementia, especially in the fact that the mind presents few or none of those insane reminiscences which are so common in dementia, and tend to give to each case distinctive features. Moreover, hallucinations, illusions, and insane ideas or delusions are by no means necessarily or even generally present. The causes of idiocy are various. Generally it depends directly on some anatomical defect, arising during intra-uterine development, or coming on shortly after birth. It may be due to injuries inflicted on the brain or its coverings. Occasionally it is the result of convulsions or epilepsy of early life, of over-forcing of the mind, of fright, or of other powerful mental impressions, or it is a sequela of some serious illness, such as one of the infectious fevers. It is often referrible to inheritance; thus, it is not uncommon among the children of parents who are close relations; it is often observed in families where other malformations, insanity, epilepsy, or tendency to scrofulous disease, prevails; and it is a frequent consequence of drunkenness of father or mother. Like goitre, it is also the product of certain localities.

Idiocy, like dementia, varies from mere feebleness of intellect to a condition in which the mind is almost wholly absent. In the latter case, the patient is apathetic, with a dull, vacant, fatuous aspect; he requires to be fed, clothed, and attended to in all particulars; he cannot speak, mumbles inarticulately, or grunts from time to time without obvious cause, or when he feels the pangs of hunger; he takes no notice of anyone or anything; he has no affections, and remembers nothing; he remains still, or performs various monotonous, meaningless movements; his sense of feeling is imperfect, his smell and taste are defective, and his hearing is obtuse; his tongue is often enlarged, and his incisor teeth protrude. His body is probably imperfectly developed, or deformed, and

certain of his muscles, or all of them, are shrunken, rigid, or paralysed. Choreic and epileptic convulsions are not infrequent. The sexual organs are usually undeveloped, though occasionally masturbation is practised. In the highest class of cases there is simple imbecility. The patient is often well developed and well grown; his nutritive functions are perfect; but he is restless and volatile, capricious in temper, clumsy in his actions, slow in the acquisition of speech, imperfect of memory and difficult to teach, awkward and inapt in the amusements and games in which his playmates delight, incapable of application or of continuous thought, and given to indulge his appetites; he is often spiteful. Between these extremes innumerable varieties exist. But they may be roughly arranged in two classes; namely, first, those who are dull and apathetic, and for the most part deformed; and, second, those who are restless and excitable, who readily respond to impressions made upon the senses, and who laugh, cry, scream, gesticulate, clap their hands, get into mischief, and at times give way to outbreaks of uncontrollable anger or fury. Idiots have been divided by Esquirol into three classes: namely, idiots who can use short words and phrases; idiots who can only utter monosyllables and certain cries; and idiots who are unable even to express themselves in monosyllables. Epilepsy is a common complication of idiocy. It is a curious circumstance, but one scarcely to be wondered at when one considers the variety of anatomical and other defects on which idiocy depends, that idiots not infrequently present special talents which *primâ facie* might appear incompatible with the presence of idiocy. Thus there are some actual, and even extreme, idiots, who manifest a real talent for the performance of music, some who have a marvellous power of drawing and painting, some who show remarkable ingenuity and skill in making models of ships or houses, some who possess an astonishing memory for dates or poetry, and some even who can perform mental calculations of considerable difficulty. Idiots, with the exception perhaps of cretins, rarely attain an advanced age. Education has a considerable influence over their condition. Most of them are capable of having the faculties they possess improved by judicious training; and it is interesting to see in well-conducted asylums how happy and useful in a way, and intelligent within certain limits, patients become, who under other circumstances would have been dirty and spiteful, and incapable of any occupation or amusement, and perhaps given to filthy habits. On the other hand, it is worthy of observation how much an idiot may retrograde under adverse conditions, how rapidly the loss of eyesight or of hearing, coming on accidentally, may reduce an idiot of the higher class to the lowest depths of mental degradation.

C. *Madness arising under special physical conditions of system.*—The subject we are now about to consider is one of great practical, and of no less scientific, importance. It is the relation between certain physiological and pathological conditions of the organism, and the quality of the insanity with which (supposing insanity to arise) they are severally likely to be associated.

Alienists recognise more or less distinct differences in the characters of insanity, according as it appears in early life, in association with child-birth, in women at the climacteric period, and in old age. They recognise obvious distinctions in insanity as it presents itself in connection respectively with hysteria, epilepsy, and self-abuse. Alcoholic insanity, and that referred to constitutional syphilis, again, severally display characteristic peculiarities. There are also special features in the madness which occasionally breaks out suddenly in the course of acute febrile disorders. The list might easily be extended.

It is not our object, nor have we space, to consider the subject at any length. In regard to some of the more important of the above varieties of insanity we have already said elsewhere (under the heads of hysteria, epilepsy, and cerebral tumours for example) all that we deem it necessary to say. In regard to others, such as that associated with syphilis, and those of youth, old age, and the cessation of the menses, the distinctive features, though doubtless real, are not sufficiently striking to be disposed of in a few simple paragraphs; and on that account mainly we pass them by. The following, however, are well-marked and easily recognisable types.

1. *Alcoholic insanity*.—We have already shown that delirium tremens (which has been described at length) is a form of acute mania. But besides this, persons who are given to drink are liable to chronic madness. Two varieties are met with. In the first the symptoms are not unlike those of delirium tremens, and come on much in the same way. They also strikingly resemble those of general paralysis of the insane. Thus, the patient has hallucinations and delusions which are often grandiose, together with muscular tremors and debility. The chief distinctions between them are, that in alcoholic insanity the delusions and hallucinations tend to be persistent, there is usually marked sleeplessness, the pupils are regular, and the patient as a rule recovers pretty rapidly under treatment. The other variety is simply dementia. It is allowable to refer here to the condition known as *Dipsomania*, wherein patients have a violent craving for drink, which is not constant, but comes on in paroxysms at irregular and sometimes long intervals. The paroxysms continue for days, sometimes for weeks; and during them the sufferer, not for the pleasures of the table or of society, but simply to satisfy his ungovernable propensity, drinks without ceasing until irritability of stomach or sheer helplessness brings his debauch to an end.

2. *Puerperal insanity*.—Madness not unfrequently becomes developed in connection with the puerperal state. Three varieties may be distinguished, according as it is connected with gestation, with child-birth, or with lactation. The first variety is commonly characterised by dislike to the husband and refusal to take food. If it comes on during the first month or two of pregnancy it usually disappears about the fourth month; if later, not until after delivery; and in either case is not benefited by premature delivery. The second variety presents certain differences according as it appears during the first few days after delivery, or after the lapse of fourteen days and later. In the first case the patient is

usually maniacal, in the second melancholic. But in either she nearly always passes, prior to recovery, into a state of partial dementia, and her physical health improves long before her mind improves. The third variety is apparently due to exhaustion arising from lactation. It is mostly melancholic, or attended with feelings of suspicion.

3. *Insanity of self-abuse*.—In this the patient usually begins by becoming weak-minded and vacillating; incapable of application; a burden to himself and others; hypochondriacally concerned about his health; solitary in his habits; avoiding society; utterly selfish, and withal not unfrequently conceited and suspicious. As the malady progresses he suffers largely from hallucinations, especially of sight and hearing; he has delusions which are to a great extent delusions of self-exaltation; and he is under influences—he is looked at, remarks are made about him, he is mesmerised, galvanised, or bewitched. Further, he often complains of his head; he has feelings there which he explains oddly; his brain is rotten, or is being peeled as though it were an onion, or his thoughts break in bubbles at the surface. In some cases the patients are impulsive and make sudden onslaughts on those about them.

4. *Insanity of febrile disorders*.—In the course of pneumonia, rheumatism, and other inflammatory affections, and in connection with some of the specific febrile diseases (not unfrequently during convalescence) patients are attacked with maniacal symptoms. These are often developed with sudden violence. As a rule, however, the mania soon passes into dementia, and sooner or later the patient recovers. But here, as in the madness of parturition, the bodily health improves before the mental health is re-established.

D. *Prognosis of insanity*.—*Idiocy* is, of course, incurable, although, as we have pointed out, such powers of mind as the sufferer possesses may often, by careful education, be improved in no inconsiderable degree. It has no necessary influence in shortening the duration of life, although as a matter of fact, owing to various causes which need not be specified, idiots as a rule die early. *General paralysis of the insane*, notwithstanding occasional cases of recovery or arrest, may also be regarded as practically incurable. We have already adverted to the fact that intermissions and periods of partial amendment are not uncommon in this disease, but as an almost universal fact general paralytics die within three years of the first appearance of symptoms. A large number die within the first year. *Dementia*, the result of advancing age, or of organic disease of the brain, may generally be regarded as incurable; although cases of dementia due to syphilitic disease of the brain occasionally recover, temporarily at any rate, under appropriate treatment. The dementia, again, which follows upon chronic melancholia, mania, and monomania is incurable. It is important to observe, however, that demented patients often live for years fairly healthy in body, and with little, or rather, perhaps, very slow deterioration of their mental state. Primary dementia—dementia due to moral shock or to acute systemic disease—is much more hopeful, as also is the partial dementia which follows upon puerperal madness, or upon

the mania of febrile disorders. Indeed, in these cases the patient generally recovers. Of the three varieties of insanity—*melancholia*, *mania*, and *monomania*—mania is the most liable to recovery; monomania the least liable. At the same time there are considerations which modify for certain cases the general applicability of this rule. For example, insanity of sudden onset is usually more curable than that which has come on insidiously; insanity which has already lasted for some time with no improvement is less hopeful than insanity of recent occurrence; cases in which mania and melancholia alternate (*folie circulaire*), and cases of recurrent insanity, are specially gloomy as to their prospects of ultimate recovery. Again, melancholia with the fixed delusion that the sufferer is the victim of some external agency, or in which under some such mental influence he has homicidal tendencies, is of ill omen. Insanity traceable to hereditary predisposition presents on the whole a less favourable prospect than insanity where no such original taint can be traced. When insanity has been brought on or aggravated by sexual excesses, and especially by self-abuse (excepting in the earliest stage of the disease), and especially when insanity is associated with epileptic fits, the chances of recovery are very faint. Madness arising in young persons, or occurring in those who are suffering from some curable bodily disorder, or developed in hysterical or puerperal females, is to a very large extent curable. It need hardly be added, that the prospects of life in insanity are largely dependent on the conditions of health associated with the mental disease; that, as has already been pointed out, tuberculosis is exceedingly common and fatal amongst insane patients; that intercurrent diseases of various kinds are apt to carry them off; that they are exposed to many accidental (suicidal or other) causes of death; and lastly, that occasionally in acute forms of insanity, attended with absence of sleep, death from simple exhaustion ensues in the course of two three weeks.

### *Pathology and Morbid Anatomy*

It is in this department of the study of insanity that our knowledge is least advanced—a fact due not to any want of skill or labour, or of admirable investigators, but to the inherent difficulty of the inquiry. We are acquainted, no doubt, with many facts which directly or indirectly throw light upon the subject. We know, for example, that it is the gray surface of the brain which is the supreme organ of all mental operations, and that in order that this shall act efficiently it is essential that the nerve-cells of the part shall be healthy in themselves and shall retain their due communication with one another, that their vascular supply, as well for nourishment as for the removal of effete matters, shall be sufficient, that they shall not be exposed to mechanical pressure or other like injurious influences, and that they shall not be acted on by poisonous matters. And we know, as the basis of these conclusions and as confirming them, that symptoms, differing little if at all from those of the several varieties of insanity which we have considered, may be caused by inflammation of the meninges or substance of the brain, by tumours affecting the same

parts, by effusions of blood, by injuries or softening involving the superficies of the brain, by anæmia due to loss of blood, by the circulation of poisonous matters retained in the blood—such as carbonic acid, bile, and urea—and by the direct action of poisons absorbed from the stomach, especially alcohol, opium, and belladonna. In true insanity, however (excluding general paralysis and idiocy, which, for reasons presently to be stated, stand in a different position, and may be regarded as distinct from it), no lesions of sufficient constancy or importance to explain the mental phenomena of the disease have ever been detected. It is not by any means that no pathological changes are discoverable in the brains of persons who have died insane. On the contrary, manifest lesions are of constant occurrence; amongst which may be enumerated, congestion, opacity, and adhesion of the visceral arachnoid and pia mater, thickening of the ependyma of the ventricles, excess of serum in the sub-arachnoid tissue, wasting of the brain, increased density and abnormal firmness of the brain-tissue, atheromatous and earthy changes in the arteries at the base, small aneurysms in the substance of the brain, evidences of the transudation of blood furnished by the presence of pigment, &c., in the course of the smaller vessels, increase of the cerebral connective tissue with the appearance of fatty molecules and corpora amylacea, atrophy of the brain-cells with pigmentation or loss of pigment, patches of sclerosis scattered here and there, extravasations of blood, abscesses and tumours. But such lesions or alterations of structure are most of them found even more frequently in the brains of persons who have never been insane, who perhaps have presented no cerebral symptoms whatever, and who have died of other than cerebral diseases. The fact is that, in patients who die of acute insanity or of insanity in the early stage, little or no change of any importance is discoverable. In many such cases the brain appears to be absolutely healthy; and, in those which present abnormal appearances, these are either simple anæmia, or more commonly congestion, pervading the pia mater, gray matter, and centrum ovale. But even when congestion is discovered, it is doubtful what relation it bears to the patient's symptoms; whether, in fact, it is their cause or their consequence. It is in the brains of patients who have died of insanity of many years' duration, and especially in the brains of such as have long been demented, and whose death is probably due to some intercurrent disorder, that the morbid changes above enumerated are almost exclusively found. The changes most commonly met with under such circumstances are those indicative of degeneration—namely, atrophy of the brain and of its essential elements, increase of the connective tissue, adhesion and opacity of the meninges, and thickening of the small vessels, with the appearance along them of corpora amylacea, fatty matter, blood-pigment, and other evidences of sanguineous exudation.

It is not, however, surprising that the post-mortem phenomena of insanity are so vague, not to say trivial. The gravity of the symptoms of disease depend, as a rule, less on the nature of the disease than on the relative importance of the organs which it implicates. And, as we well

know, so-called 'functional' disorders of the dynamical elements of the nervous centres, or disorders which depend upon molecular changes or alterations of relation which have hitherto escaped the eye, and which in themselves are often transitory and of little moment, are always attended with much more serious symptoms than similar disorders of less important parts, or even than gross diseases implicating the white substance of the brain. We need only refer in illustration to the phenomena of tetanus and poisoning by strychnia; to those of hysteria, chorea, and epilepsy; and to those arising from opium, alcohol, and other substances which act as poisons to the brain. In the same sense we may regard insanity as a functional affection of the gray matter of the surface of the brain, characterised by either exaltation, diminution, or perversion of function, and presenting subordinate differences which depend partly on the degree of functional modification present, partly on the particular areas of the brain-surface which are chiefly, or it may be solely, implicated. That insanity does not necessarily involve any profound pathological change in the texture of the brain is proved by the frequency with which rapid recovery takes place, even when the mental disturbance has been of a very aggravated kind and long maintained. At the same time there can be no doubt that insanity of long duration leads to gradual structural changes in the brain-substance, and that the supervention of such changes influences the patient's condition disastrously, and renders his restoration to mental health impossible.

Among the lesions to which insane persons are liable we may take this opportunity of adverting to one, *hæmatoma auris*, not, however, on account of its intrinsic importance, but because it is common in insanity, and characteristic of it. This, which is an effusion of blood between the cartilage and the perichondrium, and leads to much thickening and deformity of the organ, occurs in all varieties of insanity; and its occurrence is generally looked upon as of ill-omen. It has been attributed to violence, intentional or accidental, on the part of attendants; but there is no doubt that it occurs independently of this cause.

The remarks above made do not apply to general paralysis of the insane, or to most cases of idiocy, in both of which morbid conditions are usually found amply sufficient to explain the clinical phenomena manifested during life. It is now fully established that general paralysis of the insane is due directly to a kind of chronic or slow inflammation commencing in the gray matter of the surface of the brain, and either remaining limited to this or involving also other parts of the brain, and even the spinal cord. The morbid changes referred to differ little, if at all, in their essential features from the sclerosis which forms the pathological basis of *tabes dorsalis* and other varieties of chronic spinal disease. The pia mater and surface of the brain become hyperæmic, and the pia mater and arachnoid thickened and unduly adherent to each other and to the brain; the neuroglia and its corpuscles undergo abnormal development; the walls of the smaller blood-vessels partake in this change, and become thickened and incorporated with the hypertrophied connective tissue

around; the nerve-cells in the gray matter atrophy, and after a time tend to disappear; and accompanying these changes are evidences of old exudation of blood along the vessels, with fatty disintegration, and the appearance of corpora amylacea among the diseased tissues. The process is a progressive one; and it is almost needless to say that, in the changes occurring in the gray matter of the hemispheres, we have a sufficient explanation alike of the mental excitement leading on to dementia, and of the paretic trembling going on to muscular paralysis, which in association characterise the disease. It is obvious, too, to those who are at all acquainted with these affections, that there is a clinical relationship between general paralysis on the one hand, and tabes dorsalis, disseminated sclerosis, and bulbar paralysis on the other; and that many of the paralytic symptoms of general paralysis resemble those of one or other of these affections, and, at any rate, may in some cases be referred to concurrent sclerosis of the cord, medulla oblongata, and other parts of the central nervous organs.

In most cases of idiocy, excepting those due to early epilepsy, severe mental shock and other functional conditions operating after birth, there is ample explanation in the anatomical characters of the skull and brain of the mental feebleness which is present. In some cases the brain, and consequently the skull, are usually, and it may be, very remarkably small. In many cases the brain is imperfectly developed: the corpus callosum, or some other important part of it, is incomplete or absent; the posterior lobes do not cover the cerebellum; one side or part of the brain or cerebellum is atrophied; or the convolutions are few in number and simple, as they are in some of the lower animals. Sometimes the child is born with congenital hydrocephalus; or a portion of the brain, or an offset of its membranes, protrudes through a hole in the parietes of the skull. In some instances, as in cretinism, the idiocy appears to depend primarily on premature ossification of the bones at the base of the skull, and consequent interference with the due development of the brain. Sclerosis is frequently met with. Occasionally undue enlargement of the brain, without other visible change, has been observed in idiots. But even in cases of congenital idiocy it sometimes happens that no apparent defect of the central nervous organs or of their envelopes can be detected.

### *Treatment*

The treatment of insanity may be considered under two heads, namely, the moral and the therapeutical.

1. Of these the *moral treatment* is by far the most important. It is obvious that, putting out of the question our duties to the lunatic's friends and to the public, it is for his own benefit that we should protect him from the consequences of his violence or folly; and that just as it is salutary to restrain a wayward child, or a sane man's ungovernable temper, so it is salutary to the madman to put a check upon his caprices or his passions. It is from another point of view important that maniacs who are in any way dangerous or mischievous should be restrained from yielding

to their insane instincts or impulses. Our first object, in fact, in the treatment of insanity should be to remove the patient from the surroundings and associations in the midst of which his insanity arose. How this shall be best effected must depend on the nature of the case, and on the pecuniary circumstances and social position of the patient. But in all cases this removal should be accompanied by restraint. In some instances the patient, with a suitable attendant or keeper, may be allowed to travel. Change of scene, change of associations, the moral pressure which is brought to bear upon him, and the inability under which he now labours of giving play to his insane tendencies and actions, are valuable items in his treatment, and collectively often effect a cure. In some instances, where travelling is for any reason undesirable, or is forbidden by pecuniary considerations, removal in company of a skilled medical attendant to some country house or seaside place is indicated. The cases which are best treated in either of these ways are those of the several forms of insanity in their early stages, and those cases in which insanity has been caused, or is kept up, by indulgence in masturbation, drunkenness, or other vicious habits. Hysterical patients also are generally best treated away from asylums. The cases for which private treatment is especially unsuitable are those of violent mania, those of melancholia with suicidal or murderous propensities, those presenting persistent hallucinations of hearing and suspicion, those in which the patient habitually refuses food, and those in which the association with epilepsy tends to provoke sudden explosions of dangerous delirium. For most lunatics an asylum is the most suitable means of restraint and treatment; for many, because the cost of providing for their separate care is beyond the means of those who are responsible for them; and for more, because from the special characters of their malady they are best and safest treated in association with other patients, and under the rules and regulations of a well-ordered establishment. It is, no doubt, true that many patients resent incarceration, and experience a real grief and pain in being separated from their friends, and put into the society of others like themselves; but, as a matter of fact, the creation of a real cause of emotion, by taking the patient out of his unsubstantial sorrows, is not unfrequently of benefit to him; and, on the other hand, it is astonishing how soon such patients reconcile themselves to their altered circumstances. Most lunatics accept their new position as a matter of course, and without any evidence of mental suffering being awakened by it. The advantages of an asylum are obvious. The patient is deprived of the power of tyrannising over the members of his household or those who are subordinate to him; he cannot spend money lavishly or speculate, or indulge in debauchery, or commit acts of violence on himself or others; he is spared the irritating opposition or weak submission to his will of those about him; he is fed regularly and wholesomely, and compelled to keep good hours; the obvious madness of some of his companions not improbably impresses him, and the recognition of their condition may even have a beneficial effect upon his own. Moreover, patients in asylums are, according to their conditions and tastes, encouraged to spend their

time in a mixture of work and recreation which has been carefully thought out and prepared for them. Further, there is usually an ascending scale of treatment, in virtue of which patients as they improve receive more indulgence, and are regarded more and more as sane persons. In asylums, again, the facilities for treating troublesome and violent patients are much greater than they are in lodgings or even at home. In the above remarks it has been assumed that the cases under treatment are curable. For incurable patients, especially those suffering from chronic mania, dementia, or general paralysis, and for many idiots, an asylum is clearly the most appropriate place of residence. It may be added that it is not generally wise to irritate patients by opposition, or even to argue with monomaniacs on the subject of their delusions. At the same time it is well that they should see that you do not acquiesce in them.

2. The *therapeutical treatment* of insanity, on the whole, is of little specific value. And especially chronic madness, of whatever kind, rarely requires it. In insanity, however, as in other cases, possibly even more than in other cases, it is of course important to treat any bodily affection which may arise. Lunatics are not infrequently feeble and anæmic. Under such circumstances iron and quinine or other tonics are clearly called for. Tuberculosis, pneumonia, pleurisy, and other diseases are very apt to come on in the course of insanity, and to give but slight indications of their presence. It is needless to say that such maladies ought not to be overlooked, and that they demand special treatment. If the stomach or bowels be deranged, if gout or rheumatism be present, if there be uterine or ovarian disorder, if pains or aches be complained of, these several affections should be attended to. And, again, if the patient's insanity have arisen from drink or self-abuse, special therapeutic treatment will probably be desirable.

Many systems of treatment of insanity have been advocated at different times. Blood-letting, hot and cold bathing, counter-irritation, purging, and narcotism comprise the chief of those to which recourse has been had. At the present time, however, none of them is regarded as of specific value; and they are severally used in moderation only as occasion requires.

General blood-letting has fallen into disuse; but occasionally the application of the cupping-glasses or of leeches for the relief of cerebral congestion seems to be useful. Even this modified form of blood-letting, however, is seldom employed.

Baths, no doubt, are important agents. Warm baths, continued for some hours, are often useful in calming excitement. Cold baths and shower-baths, applied for not more than a minute or two at a time, are frequently beneficial in the treatment both of melancholia and of mania. Cold to the head, combined with the immersion of the body in a warm bath, is a specially valuable method of reducing excitement and promoting sleep.

Counter-irritants to the head or nape of the neck, more especially to the head, are said to be of service mainly in chronic cases.

Active systematic purging has almost fallen into desuetude. It is important, however, and necessary in many cases, to keep the bowels regulated.

Narcotics are indispensable in the treatment of insanity; but they should not be recklessly employed, for they are capable of much harm as well as of much benefit. Of these opium is by far the most valuable. The cases in which it is specially serviceable are those of commencing insanity, when the patient is sleepless and irritable and hyperæsthetic; those in which mania is subsiding; melancholic cases; and cases of insanity due to alcoholism or exhaustion. Among other narcotics or sedatives which are, or have been, employed may be enumerated: chloral hydrate, hyoscyamus, conium, digitalis, and bromide of potassium. The bromide of potassium is frequently given in combination with some one of the others, and appears often to be of service. To narcotics generally, with the exception of opium, at any rate to narcotics habitually given, Dr. Maudsley entertains serious objections.

When insane patients refuse food it becomes necessary to feed them periodically by means of the stomach-pump.

### *Legal Management of Lunatics*

1. *Places for the legal custody of lunatics.*—Patients are received into the county and borough asylums, registered hospitals, licensed houses, or single charge. In the last case (that in which the proprietor receives only one patient at a time) a licence is not required; but if the Commissioners in Lunacy are satisfied that it is desirable, and for the interest of the patient, that another patient or more than one other should reside in the same house, the proprietor may receive such other patient or patients on the same terms and conditions in all respects as if each of them were a single patient. The Lunacy Act, 1890, renders it impossible for new licences to be obtained for the reception of patients into private asylums, but existing licences may be renewed under certain circumstances. The county and borough asylums are provided for the reception of paupers; but occasionally and under special circumstances non-pauper patients are admitted into them. The act of 1889 empowers committees of asylums to make provision for non-pauper lunatics. Bethlem Hospital receives patients of the educated middle classes who are unable to pay anything, and a limited number of paying patients; St. Luke's admits such as are able to pay in part for their maintenance; and there are several other registered hospitals scattered about England in which patients are taken charge of at a cost of a pound a week and upwards. Licensed houses are mainly for the reception of paying patients, but some of them admit paupers.

2. *Private lunatics.*—No lunatic may be kept for profit unless he be under certificates. For the reception of a patient, whether into single charge, a licensed house or registered hospital, an order for his reception obtained in the following way is required, except in the case of a lunatic so found by inquisition (*see* Chancery patients).

The *order* must be made by a judge of county court, magistrate or justice of the peace specially appointed, having respectively jurisdiction in the place where the lunatic is. No relative of the person applying for

an order, or of the lunatic, can make such order. The order is to be obtained upon a private application, by petition, accompanied by a statement of particulars, and by two medical certificates. The *petition* must be presented, if possible, by the husband, or wife, or a relative of the alleged lunatic, or the reason why it is not so done must be stated. The petitioner must be at least twenty-one years of age, and must have personally seen the alleged lunatic *within fourteen days* before the presentation of the petition. He must further undertake to visit the patient personally, or by deputy, at least once in every six months.

Each *medical certificate* must be signed by some duly qualified practitioner, who is also in actual practice; and his examination of the patient must be made apart from any other practitioner. The certificate comprises two parts: first, the part containing the facts indicating insanity observed by the practitioner himself; and, second, the part containing the facts indicating insanity communicated by others. It is absolutely necessary for the signer of the certificate to state facts which he has personally observed; but in many cases these are so slight, while those observed by others are so grave, that the more weighty part of the certificate is comprised in the second part. In every case in which quoted facts are recorded, the name of the informant should be given. A certificate, if incorrect, may in most cases be amended within fourteen days of the reception of the patient. One of the certificates must, if possible, be signed by the usual medical attendant of the alleged lunatic, and if not, the reason must be stated in writing by the petitioner. No medical certificate must be signed by the petitioner, or person signing an urgency order (*vide postea*), or by a near relative of such persons; further, the practitioners signing must not be in partnership, or one the assistant of the other, or nearly related to one another, nor must they be in any way connected with the asylum, or hospital, or house, where the patient is to be received. Any wilful misstatement of fact in a medical certificate is a misdemeanour, and every medical certificate is evidence of the facts appearing therein, and of the judgment stated to have been formed, as if they had been verified on oath. Persons signing medical certificates must have personally examined the patient not more than *seven clear days* before the date of presentation of the petition, except in case of urgency (*vide postea*).

Practitioners signing certificates are not liable to civil or criminal proceedings, if they have acted in good faith and with reasonable care; but this has to be proved to the satisfaction of the court if an action is brought. For the reception of a patient in England, he must be examined and his certificates signed in England; and similarly with respect to Scotland and Ireland.

Upon the presentation of the petition, the judge, magistrate, or justice has to consider the evidence of lunacy appearing in the certificates, and whether it is necessary for him to visit and examine the alleged lunatic; if he is satisfied, he may make an order forthwith, or if not satisfied he may make such further inquiries as he may think fit, and may postpone

the consideration of the petition for not more than seven days, and may visit the alleged lunatic. He may examine witnesses on oath at the adjourned consideration of the petition, and may make an order for reception of the patient, or may dismiss the petition, or may adjourn the consideration for a further period, not exceeding fourteen days, for further evidence.

The petition must be considered in private, and all persons except the alleged lunatic, and any one person appointed by the alleged lunatic to be present, are bound to keep secret all matters and documents coming to his knowledge at the consideration.

If the petition is dismissed the judge, magistrate, or justice must state his reasons to the petitioner in writing, and must send a copy to the Commissioners in Lunacy, and if the patient has been detained under an urgency order he must send notice to the person in whose charge he is that the petition has been dismissed. If another petition is subsequently presented about the same patient, the petitioner must state the facts as to the previous dismissal, and must obtain from the Commissioners at his own expense, and present with the petition a copy of the statement sent to them of the reasons for dismissing the previous petition. A wilful failure to comply with this is a misdemeanour.

The patient must be admitted to the asylum, hospital or house before the expiration of *seven clear days* from the date of the reception order.

*Urgency orders.*—In cases of urgency, where it is deemed to be expedient that the patient, either for his own welfare or for the public safety, should be at once placed under care, he may be received and detained in an asylum, hospital, or licensed house, or as a single patient, upon an urgency order made if possible by the husband, wife, or a relative of the patient, accompanied by a statement of particulars, and one medical certificate. The practitioner signing must have personally examined the person to whom the certificate relates, not more than *two clear days* previously to his reception. The person signing the urgency order must be at least 21 years of age, and must within two days before the date of the order personally have seen the alleged lunatic, and, if not the husband, wife, or a relative, must state the reason in the order.

An urgency order may be made as well after as before a petition for a reception order has been presented. In the former case a copy of it must be at once sent to the judge, magistrate, or justice; in the latter it must be referred to in the petition. An urgency order remains in force for seven days from its date, or till the petition or application is finally disposed of.

If the patient has not been seen by the judge, magistrate, or justice, who made the order for his reception, he has the right to be taken before, or visited by, one of these officials other than the one who signed the reception order, unless the medical superintendent or medical attendant within twenty-four hours after reception sends a certificate to the Commissioners in Lunacy stating that the exercise of the right would be prejudicial to the patient. In all other cases, the responsible person

must give the patient a notice within twenty-four hours of his reception that he has this right, and the patient within seven clear days, if he desire to exercise it, must fill up a prescribed form which must be sent in a registered letter to the judge, magistrate, or justice, who may then either visit the patient or have him brought before him, and may see the medical certificates and other documents upon the consideration of which the reception order was made. He must report to the Commissioners the result of his inquiry. The neglect by the superintendent or medical attendant to perform the above duty is a misdemeanour.

A patient once under certificates can be moved from one licensed house or registered hospital to another, or to or from single charge, by means of an order of transfer. But he cannot be thus moved from one of these to an asylum, or conversely, unless as a private patient. If a pauper he must be re-certified.

Within twenty-four hours of a patient being taken charge of under certificates, notice thereof must be sent to the Commissioners, together with exact copies of the order, statement, and certificates under which he has been received; and, within seven clear days, an additional statement as to the patient's mental and bodily condition, signed by the medical superintendent or visitor, must be transmitted to them.

A further report must be sent at the end of one month and another at the end of twelve months from reception, without which latter the order for detention cannot be continued.

Letters from patients must either be kept for the inspection of the Commissioners, or, in the case of a hospital, the visiting committee, or be sent to their destination.

Mechanical means of bodily restraint must not be applied to any lunatic unless it be for surgical or medical treatment, or to prevent injury to himself or others. A medical certificate of its necessity must always be signed, and a record of its use kept and copies sent periodically to the Commissioners.

A patient in single charge must be visited once a fortnight by a medical man, unconnected with the proprietor of the house in which he is staying, and who has not signed one of the patient's certificates; and he must leave, in a book kept for the purpose, a written statement of the patient's condition and treatment and any other details that may occur to him.

The Commissioners visit every certified lunatic at least once a year.

If a patient escape from legal custody, notice must be at once sent to the Commissioners. He may be recaptured in any part of Great Britain or Ireland, the Commissioners in England or Scotland or the Inspectors of Lunacy in Ireland authorizing by writing under their seal an application to be made by such person as they shall think fit to any justice of the peace having jurisdiction in the place where the lunatic was so detained for a warrant authorizing such person to retake the lunatic and bring him back to such place.

The patient can only be retaken during the time in which he could

have been retaken according to the law in force in the place where he was detained (fourteen days in the case of escape in England).

The Commissioners may visit a patient detained in any hospital or licensed house, or as a single patient, and may, within seven days after their visit, if the patient appears to them to be detained without sufficient cause, make an order for his discharge.

An order for the examination by two medical practitioners, of any patient, may be obtained from the Commissioners upon the application of any one, whether a relative or friend or not, who shall satisfy them that it is proper for them to grant such an order; and on production of the certificates of the medical practitioners so authorized, certifying that after two separate examinations with at least seven days interval, they are of opinion that the patient may, without risk or injury to himself or to the public, be discharged, the Commissioners may order the patient to be discharged at the expiration of ten days from the date of the order.

The superintendent or proprietor of a licensed house may, with the previous consent of two of the Commissioners, or, where the house is licensed by the justices, of two of the justices, receive and lodge as a boarder for the time specified in the consent, any one who is desirous of voluntarily submitting to treatment. After the expiration of the stated time (unless consent is given for its extension) he must be discharged.

Voluntary boarders are admitted to registered hospitals without the consent of the Commissioners being obtained, but any such patient must not be certifiable on admission. Should he subsequently become certifiably insane, certificates must be obtained and the petition for a reception order presented. Notice must be sent to the Commissioners of any patient's discharge, recovery or death, and in the latter event the coroner also must be informed. Patients can be permitted to be absent on leave from asylums or hospitals with the consent of the Commissioners in Lunacy or committee. During leave of absence they are still under certificates.

3. *Lunatics wandering at large or not under proper care.*—Lunatics under certain circumstances may be dealt with summarily. If any person found wandering at large is deemed to be a lunatic (whether he be a pauper or not) he is to be taken charge of by a constable, overseer, or relieving officer. In this case he will be taken before the justices or a police magistrate, who, having called in a medical man to his assistance, will, if he think it right, on the medical man's certificate and by his own order, consign him to an asylum, registered hospital, or licensed house.

Every constable, relieving officer, or overseer of a parish who has knowledge that any person within his district, who is not a pauper and not wandering at large, is deemed to be a lunatic and is not under proper care and control, or is cruelly treated or neglected by any relative or other person, having the care and charge of him, must within three days give information upon oath to a justice specially appointed under the Lunacy Act of 1890. The justice, upon the information upon oath of any person whomsoever that this is the case, may visit the alleged lunatic and shall authorize two medical practitioners to visit and examine him

and certify as to his mental state, and may then act as if a petition for a reception order had been presented by the person giving the information.

4. *Pauper lunatics* are dealt with much in the same way as wandering lunatics. The overseer or relieving officer, generally by the direction of the parochial medical officer, takes the patient before the justices or a police magistrate, who, having called in a medical man to assist him, consigns him, at his discretion and with the foregoing formalities, to the asylum for the county or borough.

Pauper patients can no longer be admitted to asylums on the order of an officiating clergyman and overseer or relieving officer. Provision is made for allowing pauper patients to be boarded with their relatives at the expense of the guardians, the medical officer of the district of the union in which the patient is resident reporting periodically to the visiting committee of the asylum as to his treatment and condition.

5. *Chancery lunatics (so called).*—The Lord Chancellor and the Lords Justices, in virtue of an ancient prerogative of the Crown, look after imbeciles and persons of unsound mind, and administer their affairs. But before a person can be made a Chancery lunatic, a petition to the Lord Chancellor and Judges of the Supreme Court, supplemented by affidavits of medical men, has to be made. If the evidence thus furnished be sufficient the Judge in Lunacy orders an inquisition to be held by a Master in Lunacy; and notice thereof is served on the alleged lunatic, who may demand a jury, and have free communication with his solicitor. If in the result the person be found to be of unsound mind and unfit to manage his affairs, the Judge in Lunacy appoints two persons to look after his interests, the one being a committee of the person, the other a committee of the estate. The former is responsible for the lunatic's comfort and proper detention, and can have him removed from one residence to another without order of transfer or medical certificates, the only formality required being the obtaining of an official copy of the appointment of the committee of the person. Chancery lunatics are especially under the care of the Lord Chancellor's visitors, and are visited periodically by them. A report has to be periodically sent by the medical attendant to the Masters in Lunacy.

If at the inquisition it appears that the alleged lunatic is of unsound mind, so as to be incapable of managing his affairs, but that he is capable of managing himself, and is not dangerous to himself or others, it may be so found and certified, a committee of the estate only being appointed. The Judge in Lunacy may upon sufficient evidence that any lunatic lawfully detained, or any person not so detained and not already found lunatic by inquisition, is incapable of managing his estate and affairs, make an order that the next friend may on behalf of the patient exercise the powers of a committee of the estate as if the patient had been found lunatic by inquisition.

If a person who has been proved by inquisition to be a lunatic recovers, a writ of 'supersedeas' is issued upon medical affidavits; if however the Judge in Lunacy is satisfied that the patient is capable of managing him-

## MEDICAL CERTIFICATE.

In the matter of A. B., of <sup>1</sup>  
in the County <sup>2</sup> of <sup>3</sup>  
an alleged lunatic.

<sup>1</sup> Insert residence of patient.

<sup>2</sup> City or borough as the case may be.

<sup>3</sup> Insert profession or occupation if any.

<sup>4</sup> Insert the place of examination, giving the name of the street, with number or name of house; or, should there be no number, the Christian and surname of occupier.

<sup>5</sup> City or borough as the case may be.

<sup>6</sup> Omit this where only one certificate is required.

<sup>7</sup> If the same or other facts were observed previous to the time of the examination, the certifier is at liberty to subjoin them in a separate paragraph.

<sup>8</sup> The names and Christian names (if known) of informants to be given with their addresses and descriptions.

<sup>9</sup> Strike out this clause in case of a private patient whose removal is not proposed.

<sup>10</sup> Insert full postal address.

I, the undersigned C. D., do hereby certify as follows:

1. I am a person registered under the Medical Act, 1858, and I am in the actual practice of the medical profession.  
2. On the \_\_\_\_\_ day of \_\_\_\_\_ 18\_\_\_\_, at <sup>4</sup>  
\_\_\_\_\_ (separately from any other Practitioner) <sup>6</sup> I personally examined the said A. B., and came to the conclusion that he is a (lunatic, an idiot, or a person of unsound mind), and a proper person to be taken charge of and detained under care and treatment.

3. I formed this conclusion on the following grounds, viz.:

(a) Facts indicating insanity observed by myself at the time of examination, <sup>7</sup> viz.:

(b) Facts communicated by others, viz.:

[If an urgency certificate is required it must be added here.]

4. The said A. B. appeared to me to be (or not to be) in a fit condition of bodily health to be removed to an asylum, hospital, or licensed house.<sup>9</sup>

5. I give this Certificate, having first read the section of the Act of Parliament printed below.

SIGNED, C. D., of <sup>10</sup>

DATED

self, but incapable of managing his affairs, he may supersede the inquisition so far as relates to the commitment of the person of the lunatic.

There is no advantage in making a person a Chancery lunatic unless the prospect of cure be very remote, or important and pressing pecuniary interests be involved ; for the proceeding is slow and costly, and is not easy to revoke.

*Extract from Section 317 of the Lunacy Act, 1890.*

Any person who makes a wilful misstatement of any material fact in any medical or other certificate, or in any statement or report of bodily or mental condition under this Act, shall be guilty of a misdemeanour.

*Statement accompanying Urgency Order.*

I certify that it is expedient for the welfare of the said A. B. (or for the public safety, *as the case may be*), that the said A. B. should be forthwith placed under care and treatment. My reasons for this conclusion are as follows. (State them.)

   — treatment of, 1229  
   — varieties of, 1215  
 Demodex folliculorum, 353  
 Dengue, 200  
   — causation of, 200  
   — definition of, 200  
   — diagnosis of, 201  
   — history of, 200  
   — symptoms and progress of, 200  
   — treatment of, 201  
 Dentition, inflammation of gums in, 645  
 Derangements, functional, 94, 98  
   — mechanical, 94  
 Development in health, 21  
 Dextrose in urine, 835  
 Diabetes, 886  
   — causation of, 886  
   — definition of, 886  
   — morbid anatomy of, 889  
   — pathology of, 889  
   — symptoms and progress of, 886  
   — treatment of, 891  
   — insipidus, 892  
   — — causation of, 892  
   — — definition of, 892  
   — — morbid anatomy of, 893  
   — — symptoms and progress of, 893  
   — — treatment of, 893  
 Diabetic coma, 889  
 Diarrhœa, 773  
   — causation of, 773  
   — infantile, 776  
   — pathology of, 773

## DIA

- Diarrhœa, premonitory, of cholera, 238  
 — symptoms and progress of, 774  
 — treatment of, 777  
 Dickinson on acute Bright's disease, 859  
 — on alcohol and renal disease, 626  
 — on brain in diabetes, 890  
 — on chorea, 1121  
 — on lardaceous degeneration, 86  
 — on rickets, 931  
 — on tetanus, 1158  
 Digestive organs, diseases of, 636 *et seq.*  
 Dilatation of arteries (*see* Aneurysm), 553  
 — of heart (*see* also Aneurysm of Heart), 498, 500, 517, 519  
 — of lymphatics (*see* Lymphatic Vessels, dilatation of), 602  
 — of œsophagus, 657  
 — of stomach, 738  
 — of urinary bladder, 897  
 — of uterus, 900  
 — of veins (*see* Varix), 566  
 Diphtheria, 208  
 — affection of air-passages in, 211  
 — — of deep tissues about neck in, 213  
 — — of external parts in, 213  
 — — of fauces and pharynx in, 211  
 — — of kidneys in, 217  
 — — of mouth in, 211  
 — — of nose in, 213  
 — — of œsophagus in, 211  
 — albuminuria in, 214  
 — bacteria in, 216  
 — causation of, 208  
 — causes of death in, 212, 213  
 — collapse of lungs in, 217  
 — definition of, 208  
 — duration of, 214  
 — history of, 208  
 — incubation of, 209  
 — lobular pneumonia in, 217  
 — malignant, 213  
 — morbid anatomy of, 216  
 — mortality of, 214  
 — paralytic affections in, 215, 1074  
 — pathology of, 216  
 — structure of false membrane in, 216  
 — symptoms and progress of, 209  
 — tracheotomy in, 218  
 — treatment of, 217  
 — varieties of, 211  
 Diphtherite (*see* Diphtheria), 208  
 Dipsomania, 1224  
 Disease, ætiology of, 7  
 — change of type in, 13  
 — definition of, 3  
 — physiological processes in, 23  
 — treatment of, 122  
 Diseases of arteries, 549 *et seq.*  
 — of blood, 576 *et seq.*  
 — of digestive organs, 636 *et seq.*  
 — of ductless glands, 576 *et seq.*  
 — of genito-urinary organs, 827 *et seq.*

## DRU

- Diseases of heart, 485 *et seq.*  
 — of kidneys, 827 *et seq.*  
 — of liver 779, *et seq.*  
 — of locomotory organs, 906 *et seq.*  
 — of lymphatics, 598 *et seq.*  
 — of mouth, fauces, &c., 636 *et seq.*  
 — of nervous system, 939 *et seq.*  
 — of œsophagus, 655 *et seq.*  
 — of pancreas, 825 *et seq.*  
 — of pelvic organs, 895 *et seq.*  
 — of respiratory organs, 365 *et seq.*  
 — of skin, 294 *et seq.*  
 — specific febrile, 133 *et seq.*  
 — of spleen, 592 *et seq.*  
 — of stomach, intestines, and peritoneum, 662 *et seq.*  
 — of supra-renal capsules, 588  
 — of thyroid body, 579  
 — of urinary bladder, 896  
 — of uterus, Fallopian tubes, and ovaries, 898  
 — of vascular organs, 485 *et seq.*  
 — of veins, 565 *et seq.*  
 Disinfection, 144 *et seq.*  
 Displacement of heart, 495  
 Dissecting aneurysm, 563  
 Disseminated sclerosis (*see* Sclerosis, Disseminated), 1063  
 Districts, cell-, 20  
 Dittrich on diffusion of tubercle, 80  
 Diuresis (*see* Diabetes insipidus), 892  
 — in hysteria, 1146  
 Doehmius duodenalis, 728  
 — symptoms of, 728  
 Donkin on diabetes, 892  
 Double vision in oculo-motor paralysis, 1174 *et seq.*  
 Drink as a cause of disease, 10  
 Dropped hand (*see* Lead-poisoning), 627  
 629  
 Dropsy, 100  
 — abdominal (*see* Ascites), 758  
 — anæmic, 101  
 — anasarca, 100  
 — cardiac, 101  
 — cerebral (*see* Hydrocephalus), 1110  
 — general, 100  
 — local, 102  
 — lymphatic, 103  
 — of larynx, 468  
 — of lungs, 468  
 — of respiratory organs, 467  
 — — — causation of, 467  
 — — — morbid anatomy of, 467  
 — — — symptoms of, 468  
 — — — treatment of, 469  
 — pericardial, 540  
 — pleural, 468  
 — pulmonary, 101  
 — renal, 101  
 — in scarlet fever, 169  
 — spinal (*see* Hydrorrhachis), 1110  
 Drunkard's liver (*see* Cirrhosis), 792

## DRY

- Dry gangrene, 93  
 — mouth, 652  
 Duchenne on deltoid rheumatism, 1181  
 — on dropped hand, 630 *et seq.*  
 — on functional spasm, 1184  
 — on glosso-labio-laryngeal palsy, 1057 *et seq.*  
 — on infantile paralysis, 1037  
 — on locomotor ataxy, 1054 *et seq.*  
 — on neuralgia, 1190  
 — on paralysis of musculo-spiral nerve, 1181  
 — — — of portio dura, 1178 *et seq.*  
 — on progressive muscular atrophy, 1040 *et seq.*  
 — on pseudo-hypertrophic paralysis, 1079 *et seq.*  
 — on spinal paralysis (of adults), 1038  
 — (fils) on infantile paralysis, 1034  
 Duckworth on fat in urine, 845  
 — on tinea tonsurans, 355  
 Ductless glands, diseases of, 576 *et seq.*  
 Ducts, hepatic, inflammation of, 785  
 — — — obstruction of, 817  
 — pancreatic, dilatation of, 826  
 — — — obstruction of, 826  
 Dulness on percussion, 380, 381  
 Dupré on elimination of alcohol, 626  
 Dura mater, inflammation of, 1006  
 — — — causation of, 1006  
 — — — morbid anatomy of, 1006  
 — — — morbid anatomy of (cerebral), 1006  
 — — — morbid anatomy of (chronic), 1007  
 — — — morbid anatomy of (spinal), 1006  
 — — — symptoms and progress of, 1008  
 — — — symptoms and progress of acute (cerebral), 1008  
 — — — symptoms and progress of acute (spinal), 1010  
 — — — symptoms and progress of chronic (cerebral), 1010  
 — — — symptoms and progress of chronic (spinal), 1013  
 — — — symptoms and progress of (in vertebral caries), 1011  
 — — — treatment of, 1013  
 Dysæsthesia, 980  
 Dyscrasia, primary, 29  
 — secondary, 30  
 Dysentery, 689  
 — causation of, 689  
 — definition of, 689  
 — morbid anatomy of, 690  
 — sequelæ of, 694  
 — symptoms and progress of, 692  
 — terminations of, 693  
 — treatment of, 694  
 Dyspepsia, 764  
 — appetite in, 767  
 — causation of, 765  
 — definition of, 764

## ELE

- Dyspepsia, eructation in, 768  
 — flatulence in, 768  
 — nausea in, 768  
 — pain and uneasiness in, 767  
 — pyrosis in, 769  
 — sickness in, 768  
 — symptoms of, 767  
 — treatment of, 770  
 Dysphagia, 658  
 Dyspnœa, 369  
 EAR, disease of, causing encephalitis, 1026 *et seq.*  
 — — — causing meningitis, 1006, 1008 *et seq.*  
 Echondrosis, 56  
 Ecchymosis, meaning of term, 295  
 Echinococcus, description of, 723  
 Eclampsia, 1123, 1135, 1163  
 — causation of, 1135  
 — definition of, 1135  
 — symptoms and progress of, 1135  
 — treatment of, 1136  
 Ecstasy, 1152, 1153  
 — treatment of, 1154  
 Ecthyma (*see* Impetigo), 321  
 Eczema, 318  
 — acute, 319  
 — causation of, 318  
 — chronic, 319  
 — description of, 318  
 — identity of, with lichen and strophulus, 318  
 — impetiginodes, 319  
 — lichen agrius, a variety of, 319  
 — — — circumscriptus, a variety of, 319  
 — — — simplex, a variety of, 319  
 — — — marginatum parasitarium, 359  
 — rubrum, 319  
 — strophulus confertus, a variety of, 319  
 — — — intertinctus, a variety of, 319  
 — — — voluticus, a variety of, 319  
 — treatment of, 320  
 Electric contractility of paralysed muscles, 1002  
 — reaction of degeneration, 1002  
 — sensibility of paralysed muscles, 1003  
 Electricity in nervous diseases, 998 (*see also* various disorders)  
 — for diagnosis, 1001  
 — faradic or induced, 999  
 — galvanic or continuous, 999  
 — as sedative, 1005  
 — as stimulant, 1003  
 — for therapeutical purposes, 1003  
 Elephantiasis, 337  
 — affection of lymphatics in, 338  
 — Arabum (*see* Elephantiasis), 337  
 — causation of, 337  
 — description of, 337  
 — Græcorum (*see* Leprosy), 276  
 — lymphangiectodes, 338, 733

## ELE

- Elephantiasis lymphangiectodes, affection  
 of lymphatics in, 339  
 — — filariæ in blood in, 339  
 — treatment of, 339  
 Elephas (*see* Elephantiasis), 337  
 Elimination, 127  
 Elliotson on hay-asthma, 483  
 — on iron in paralysis agitans, 1078  
 Embolism, 567, 570  
 — and chorea, 1120  
 — causation of, 570  
 — consequences of, 571  
 — morbid anatomy of, 570  
 — multiple, 575  
 — of cerebral arteries (*see* Cerebral Arteries, Obstruction of), 1104  
 — pulmonic, 573  
 — pyæmic, 270  
 — symptoms of, 571 *et seq.*  
 — systemic, 574  
 Emotional disturbance, pathology of, 998  
 Emphysema of lungs, 461  
 — — causation of, 461  
 — — interlobular, 461  
 — — morbid anatomy of, 461  
 — — symptoms and progress of, 465  
 — — treatment of, 466  
 — — vesicular, 462  
 — — varieties of, 462  
 Emprosthotos, 1157  
 Empyema, 424 *et seq.*  
 Encephalitis, 1025  
 — causation of, 1025  
 — morbid anatomy of, 1025  
 — symptoms and progress of, 1027  
 — treatment of, 1031  
 Encephaloid cancer, 70 (*see also* Morbid Growths)  
 Enchondroma, 55  
 Endemic, in relation to fevers, 133  
 Endoarteritis, 550  
 — causation of, 550  
 — morbid anatomy of, 550  
 — symptoms of, 551  
 — syphilitic, 551  
 Endocarditis, 527  
 — causation of, 527  
 — morbid anatomy of, 527  
 — prognosis of, 529  
 — symptoms and progress of, 528  
 — treatment of, 530  
 — ulcerative, 575  
 Endopathic causes of disease, 14, 15  
 Enostosis, 57  
 Enteric fever, 219  
 — — causation of, 219  
 — — causes of death in, 227  
 — — complications of, 227  
 — — decomposing fæces in relation to, 220  
 — — definition of, 219  
 — — diagnosis of, 219  
 — — history of, 219

## EPI

- Enteric fever, incubation of, 221  
 — — intestinal disease in, 228  
 — — intestinal hemorrhage in, 226  
 — — intestinal perforation in, 226  
 — — mesenteric gland affection in, 230  
 — — morbid anatomy of, 228  
 — — mortality in, 227  
 — — peritonitis in, 226  
 — — pulmonary affection in, 227  
 — — spleen, enlargement of, in, 230  
 — — symptoms and progress of, 221  
 — — treatment of, 230  
 — — varieties of, 225  
 — — vegetable organisms in, 230  
 Enteritis, 671  
 — catarrhal, 671, 672  
 — causation of, 671  
 — morbid anatomy of, 671  
 — symptoms and progress of, 672  
 — chronic, 672  
 — pellicular, 671, 673  
 — phlegmonous, 672, 673  
 — treatment of, 675  
 Entozoa (*see* Parasites and Parasitic Diseases, or Morbid Growths of Different Organs)  
 Epidemic catarrh (*see* Influenza), 147  
 — cerebro-spinal meningitis (*see* Cerebro-spinal fever), 205  
 — cholera, 233  
 — — algide stage in, 239  
 — — causation of, 233  
 — — collapse in, 238  
 — — death in, 239, 240  
 — — definition of, 233  
 — — diagnosis of, 241  
 — — epidemic extension of, 233  
 — — history of, 233  
 — — incubation of, 238  
 — — injection of saline fluids in, 245  
 — — Koch's investigations in, 238  
 — — morbid anatomy of, 242  
 — — mortality of, 241

 — — specific organisms in, 238  
 — — symptoms and progress of, 238  
 — — telluric and atmospheric causes of, 234  
 — — Thiersch, experiments as to transmission of, 237  
 — — treatment of, 244  
 — — varieties of, 241  
 Epidemic constitution, 12

## EPI

- Epidemic diseases, management of, 144  
 — in relation to fevers, 133  
 — roseola, 160  
 — — causation of, 160  
 — — definition of, 160  
 — — diagnosis of, 161  
 — — incubation of, 160  
 — — symptoms and progress of, 160  
 Epilepsia gravior, 1125  
 — mitior, 1127  
 Epilepsy, 1123  
 — causation of, 1123  
 — definition of, 1123  
 — diagnosis of, 1131  
 — feigned, 1132  
 — morbid anatomy of, 1132  
 — pathology of, 1132  
 — spinal in disseminated sclerosis, 1067  
 — — in lateral sclerosis, 1047  
 — symptoms and progress of, 1124  
 — treatment of, 1134  
 Epileptic attack, description of, 1124  
 — — clonic convulsions in, 1126  
 — — coma in, 1125  
 — — cry in, 1126  
 — — exciting causes of, 1130  
 — — recurrence of, 1129  
 — — tonic convulsions in, 1125  
 — aura, 1124  
 — mania, 1130  
 — state, 1129  
 — vertigo, 1127  
 — — varieties of, 1127  
 Epileptiform neuralgia (*see* Tic Douloureux), 1185, 1188  
 Epithelial tissues, 19  
 Epithelioma (*see also* Morbid Growths), 72  
 Equinia (*see* Glanders), 252  
 Erb on electric irritability of nerves, 1003  
 — lateral sclerosis, 1048  
 — on tendon reflex, 971  
 — on tetany, 1161  
 — on Thomsen's disease, 1082  
 Erectile tumours, 59  
 Erysipelas, 299  
 — a specific fever, 299  
 — bacteria in, 299  
 — causation of, 299  
 — contagiousness of, 299  
 — definition of, 299  
 — erratic, 300  
 — hypertrophy in, 301  
 — idiopathic, 299  
 — in small-pox, 175  
 — larynx, involvement of, in, 301  
 — meninges, involvement of, in, 301  
 — morbid anatomy of, 300  
 — phlegmonous, 303  
 — pneumonia in, 301  
 — serous membranes, extension of, to, 301  
 — simple, 302

## EYE

- Erysipelas, symptoms and progress of, 301  
 — traumatic, 299  
 — treatment of, 303  
 — varieties of, 302  
 — veins, extension of, to, 301  
 Erythema, 306  
 — causation of, 306  
 — circinatum, 307 (*see also* Tinea Tonsurans, 353)  
 — description of, 306  
 — fugax, 309  
 — gyratum, 308  
 — identity of, with roseola, urticaria, and pityriasis, 306  
 — in nervous diseases, 983 *et seq.*  
 — in rheumatism, 910  
 — intertrigo, 307  
 — iris, 307  
 — læve, 307  
 — marginatum, 308  
 — multiforme, 307  
 — nodosum, 308  
 — papulatum, 307  
 — pityriasis capitis, a form of, 307  
 — — simplex, a form of, 306  
 — purpura urticans, a variety of, 308  
 — roseola, a variety of, 309  
 — — autumnalis, a variety of, 309  
 — simplex, 306  
 — treatment of, 310  
 — tuberculatum, 309  
 — urticaria, a variety of, 309  
 Erythrasma, 359  
 — causation and description of, 359  
 — microsporon minutissimum in, 359  
 Esquirol on madness, 1191 *et seq.*  
 Essential anæmia (*see* Anæmia), 607  
 — paralysis (*see* Paralysis, Spinal Infantile), 1034  
 Etiology of disease, 7  
 Eulenberg on pulse in tabes dorsalis, 1053  
 Ewart, Cossar, on bacillus anthracis, 139  
 Exanthem, or exanthema, meaning of term, 295  
 Exanthemata, Willan's third order, 295  
 Exciting causes, 7, 13  
 Excretion in health, 22  
 Exopathic causes of disease, 14, 15  
 Exophthalmic goitre (*see* Graves's Disease), 576  
 Exostosis, 57  
 Expectoration, 371  
 — bloody, 372  
 — fetid, 373  
 — nummulated, 371  
 — of foreign bodies, 372  
 — plastic (casts of tubes), 372  
 — pneumonic, 372  
 — purulent, 373  
 Exudation, inflammatory, 40  
 Eyes, affection of, in syphilis, 259, 264  
 — — in disseminated sclerosis, 1066

## EYE

- Eyes, affection of, in inflammation of dura mater, 1009, 1010  
 — in meningitis, 1018 *et seq.*  
 — in morbid growths of the brain, 1089  
 — in oculo-motor paralysis, 1172  
 — in renal disease, 849  
 — in spinal disease, 1012  
 — in tabes dorsalis, 1052  
 — conjugate deviation of, in cerebral hæmorrhage, 1099  
 — — — in destructive lesions, 958

**F**ACIAL neuralgia (*see* Tic Douloureux), 1185, 1188  
 — palsy (*see* Paralysis of the Portio Dura), 1177

- Fagge, H., on compression of bowel, 745  
 — on scleroderma, 336  
 — on sporadic goitre, 585  
 — on xanthoma, 334  
 — and Durham on electrolytic treatment of hydatid cysts, 808

Fallopian tubes, dilatation of, 900  
 — — tubercle of, 899

Falret on epileptic mania, 1130  
 — on madness, 1206, 1217

Famine fever (*see* Relapsing Fever), 196

Faradic (*see* Electric)

Faradism (*see* Electricity)

Farcy (*see* Glanders), 252

Fatty degeneration, 86

— of heart, 534

— — — symptoms of, 535

— — — treatment of, 537

— of liver (*see* Liver, Fatty), 809

— growth of heart, 531

— — — symptoms of, 531

— tumour, 53

Fauces, gangrene of, 643, 644

— — causation of, 644

— — symptoms and progress of, 644

— — treatment of, 645

— malignant tumours of, 654

— syphilitic disease of, 653

— tubercle of, 653

Favus (*see* Tinea Favosa), 356

Febris rubra (*see* Scarlet Fever), 162

Fehling's test for sugar, 836

Ferrier on localisation of cerebral functions, 954 *et seq.*

Fever, 103

— blood in, 108

— causes of death in, 109, 110

— causes of high temperature in, 110

— cerebro-spinal (*see* Cerebro-spinal Fever), 205

— crisis in, 109

— dandy (*see* Dengue), 200

 — — — diagnosis of, 1182  
 — — — pathology of, 1185  
 — — — symptoms of, 1182  
 — — — treatment of, 1185  
 Fungus disease of India, 737  
 Furfura, meaning of term, 297  
 Furunculus (*see* Carbuncle), 304  
 Fusible calculus, 847

**G** AIRDNER, on asthma, 482

- on delirium tremens, 626  
 — on presystolic murmur, 506  
 — on pulmonary collapse, 470  
 Galabin on pulse-trace, 491 *et seq.*  
 Gall-bladder, dilatation of, 817  
 — — mucous cyst of, 818  
 — — shrivelling of, 817  
 — — ducts (*see* Hepatic Ducts), 786, 817  
 — — stones, 811  
 — — — causation of, 812  
 — — — chemical constitution of, 813  
 — — — consequences of, 814  
 — — — impaction of, in bowels (*see* Impaction of Foreign Bodies in Bowels), 748  
 — — — morbid anatomy of, 812  
 — — — size and shape of, 812  
 — — — symptoms and progress of, 814  
 — — — treatment of, 816  
 Galvanic (*see* Electric)  
 Galvanism (*see* Electricity)  
 Gangrene, 43, 91  
 — in leprosy, 281  
 — of fauces, *see* Fauces, Gangrene of), 643, 644  
 — of lung, in pneumonia, 414 *et seq.*

## GLU

- Gangrene of mouth, 643  
 Garrod on gout, 918 *et seq.*  
 — on lead-poisoning, 628 *et seq.*  
 — on rheumatism, 911  
 — on rheumatoid arthritis, 917  
 — on scurvy, 620  
 Gastric (*see* Stomach)  
 Gastritis, 666  
 — causation of, 666  
 — morbid anatomy of, 667  
 — symptoms and progress of, 667  
 — — — of acute, 667  
 — — — of chronic, 669  
 — — — of mild, 668  
 — — — treatment of, 669  
 Gastrodynia, 767, 772  
 Gayton on vaccination, 184  
 Gee on scarlet fever, 166  
 General paralysis of the insane, 1217  
 — causes of death in, 1222  
 — congestive form of, 1217  
 — duration of, 1221  
 — expansive form of, 1219  
 — melancholic form of, 1220  
 — morbid anatomy of, 1228  
 — paralytic form of, 1217  
 — prognosis of, 1225  
 — treatment of, 1229  
 — varieties of, 1217  
 Generalisation of morbid growths, 26  
 Genito-urinary organs, diseases of, 827 *et seq.*  
 Giant-cells in tubercle, 76  
 Gibbes's process for detecting bacillus of tubercle, 82  
 Gingivitis, 645  
 Glanders, 252  
 — causation of, 252  
 — chronic form of, 253  
 — definition of, 252  
 — farcy, 253  
 — history of, 252  
 — incubation of, 252  
 — morbid anatomy of, 254  
 — results of, 254  
 — symptoms and progress of, 252  
 — treatment of, 254  
 — tubercles of (farcy-buds), 253  
 Glandular laryngitis, 397  
 Glioma, 55  
 Globus hystericus, 1142  
 Glossitis, 646  
 — causation of, 646  
 — symptoms and progress of, 646  
 — treatment of, 647  
 Glosso-labio-laryngeal palsy, 1057  
 — — causation of, 1057  
 — — definition of, 1057  
 — — morbid anatomy of, 1057  
 — — symptoms and progress of, 1058  
 — — treatment of, 1060  
 Glossy skin, 362, 984  
 Glucose in urine, 835

## GLU

- Glue-like tumour, 55  
 Glycosuria (*see* Diabetes), 886  
 Goitre, 579  
 — causation of, 579  
 — exophthalmic, (*see* Graves's Disease), 576  
 — morbid anatomy of, 580  
 — sub-maxillary, 582  
 — sub-sternal, 582  
 — symptoms and progress of, 581  
 — treatment of, 582  
 — varieties of, 580  
 Gonorrhœal rheumatism, 912  
 Goodeve on raw meat in diarrhœa, 778  
 Goodhart on syphilitic disease of lungs, 451  
 — on keloid, 333  
 Gout, 917  
 — causation of, 918  
 — chalk-stones (or tophi) in, 919  
 — definition of, 917  
 — morbid anatomy of, 919  
 — pathology of, 924  
 — symptoms and progress of, 920  
 — treatment of, 925  
 Gowers on hydrophobia, 249  
 — on leucocythæmia, 604, 605  
 — on ophthalmoplegia, 1061  
 — on reflex action, 972  
 — on spinal cord, 948  
 — on Thomsen's disease, 1082  
 Gräfe, von, on Graves's disease, 577  
 — — on ophthalmoplegia, 1060  
 Grandidier on hæmophilia, 613  
 Granular degeneration of heart, 535  
 — pharyngitis (*see* Pharyngitis, Granular), 647  
 Granulation, 44  
 — tumour, 74  
 Granuloma, 74  
 — fungoides, 346  
 Grape-sugar in urine, 835, 887  
 Gravel (*see* Urinary Concretions), 874  
 Graves on Chorea, 1116  
 Graves's disease, 576  
 — — causation of, 576  
 — — definition of, 576  
 — — enlargement of thyroid in, 577  
 — — insanity in, 578  
 — — morbid anatomy of, 577  
 — — palpitation in, 577  
 — — protrusion of eyeballs in, 577  
 — — symptoms and progress of, 577  
 — — treatment of, 578  
 Greenfield on bacillus anthracis, 139  
 — on hydrophobia, 249  
 — on mitigation of contagium, 140  
 — on syphilitic disease of lungs, 451  
 — — on syphilitic endoarteritis, 551  
 Greenhow, H., on cirrhosis of lungs, 433  
 — — on paracentesis of hydatid cysts, 808  
 Green-sickness (*see* Anæmia), 607

## HAL

- Gregory on statistics of small-pox inoculation, 180  
 Grey hepatisation of lung, 412 *et seq.*  
 — induration of lung, 432  
 Griesinger on madness, 1190 *et seq.*  
 Griffin, Messrs., on spinal irritation, 1147  
 Grocer's itch, 310  
 Growth in health, 18, 21  
 — morbid (*see* Morbid Growth), 24  
 Growths, morbid (*see* Tumours), 50 *et seq.* (*see also* Morbid Growths and Tumours of different organs)  
 Grube on Filaria, 732  
 Guerin on rickets in puppies, 927  
 Guislain on madness, 1203  
 Gull, Sir W., on factitious urticaria, 310  
 — — — on hydrorrhachis, 1115  
 — — — on myxœdema, 586 *et seq.*  
 — — — on vitiligoidea, 334  
 — — — and Dr. Sutton on abscess of brain, 1026  
 — — — and Dr. Sutton on hyaline-fibroid change of vessels, 848  
 Gummata, 82  
 Gums, inflammation of, 645  
 Gurgling, 393

- H**ABITS as causes of disease, 10  
 Hadden, Dr., on anatomy of spinal cord, 948  
 — on 'dry mouth,' 652  
 Hæmatemesis (*see* Hemorrhage from Stomach, &c.), 762  
 Hæmatinuria, paroxysmal (*see* Hæmoglobinuria)  
 Hæmatoidine crystals, 88  
 Hæmatoma auris, 1228  
 Hæmaturia, 841, 882  
 — causation of, 882  
 — symptoms of, 882  
 — treatment of, 883  
 — paroxysmal (*see* Hæmoglobinuria)  
 Hæmic murmurs, 511  
 Hæmoglobinuria, paroxysmal, 883  
 — — causation of, 883  
 — — definition of, 883  
 — — pathology of, 885  
 — — symptoms and progress of, 883  
 — — treatment of, 885  
 Hæmophilia, 612  
 — causation of, 612  
 — definition of, 612  
 — morbid anatomy of, 613  
 — symptoms and progress of, 612  
 — treatment of, 613  
 Hæmoptysis, 372 (*see also* Hemorrhage of Respiratory Organs), 471  
 Hæmorrhage (*see* Hemorrhage)  
 Haig-Brown on quinsy, 649  
 Haldane on carbonate of lime calculi, 847  
 Halford, Sir H., on catarrh, 639  
 Hall, Marshall, on epilepsy, 1133

## HAL

- Hallier on oïdium albicans, 640  
 Hammond on athetosis, 978  
 Hanot on hypertrophic cirrhosis, 794  
 Hansen on bacillus lepræ, 278  
 Hare on treatment of hysteria, 1150

 — hemiplegia in, 1144  
 — hyperæsthesia in, 1142  
 — joints, affection of, in, 1147  
 — larynx, affection of, in, 1145  
 — mammae, affection of, in, 1147  
 — mania in, 1141  
 — mental condition in, 1139  
 — ovaries, condition of, in, 1143  
 — paralysis in, 1144

## INF

- Hysteria, paraplegia in, 1144  
 — pathology of, 1149  
 — reproductive organs, affection of, in, 1147  
 — spasms in, 1141  
 — speech, affection of, in, 1145  
 — spinal irritation in, 1147  
 — spine, affection of, in, 1147  
 — suppression of urine, in, 1146  
 — symptoms and progress of, 1139  
 — treatment of, 1149  
 — urinary organs, affection of, in, 1146  
 Hystero-epilepsy, 1141

## ICHOR, 42

- Ichthyosis, 314  
 — cornea, 315  
 — simplex, 314  
 — treatment of, 315  
 Icterus (*see* Jaundice)  
 Idiocy, 1222  
 — causes of, 1222  
 — morbid anatomy of, 1229  
 — prognosis of, 1225  
 — treatment of, 1229  
 — varieties of, 1223  
 Idiopathic anæmia (*see* Anæmia), 607  
 Impaction, 95  
 — of foreign bodies in bowels, 748  
 — — — causation of, 748  
 — — — morbid anatomy of, 748  
 — — — symptoms and progress of, 749

— — — treatment of, 755

## Impetigo, 321

- causation of, 321  
 — description of, 321  
 — erysipelatodes, 322  
 — figurata, 322  
 — porrigo larvalis, 322  
 — scabida, 322  
 — sparsa, 322  
 — sycosis, 322  
 — treatment of, 322

## Impure air as cause of disease, 11

## Indican in urine, 835

Indigestion (*see* Dyspepsia), 764

## Indigo in urine, 835

— calculus, 847

## Induration, black, of lungs, 432

- brown, of lungs, 432  
 — grey, of lungs, 432  
 — red, of lungs, 432

## Infantile convulsions, 1123, 1136

- — causation of, 1136  
 — — definition of, 1136  
 — — symptoms and progress of, 1137  
 — — treatment of, 1137  
 — paralysis (*see* Paralysis, Spinal, Infantile), 1034

## Infection, in relation to fevers, 134

## Inflammation, general pathology of, 34

## INF

- Inflammation, abscess in, 42  
 — cause of change of size in vessels in, 39  
 — — — varying rates of blood-flow in, 39  
 — cicatrization after, 45  
 — constitutional effects of, 46  
 — destructive processes in, 42  
 — extravascular processes in, 35  
 — exudation in, 40  
 — gangrene in, 43  
 — granulation in, 44

 — of kidney, chronic (*see* Chronic Bright's Disease), 859  
 — of larynx (*see* Laryngitis), 396  
 — of liver (*see* Hepatitis), 787  
 — — chronic (*see* Cirrhosis), 792  
 — of lungs (*see* Pneumonia), 410  
 — — chronic (*see* Cirrhosis), 430  
 — of lymphatics (*see* Lymphatics, Inflammation of), 598  
 — of meninges (*see* Meningitis), 1015  
 — of mouth, fauces, &c. (*see* Catarrh, Thrush, Stomatitis, Noma), 636, 639, 641, 643  
 — of muscular walls of heart (*see* Myocarditis), 526  
 — nerves (*see* Multiple Neuritis), 1070  
 — of nervous centres, chronic (*see* Sclerosis), 1032  
 — of œsophagus (*see* Œsophagus, Inflammation of), 655

## IRR

- Inflammation of œsophagus, ulcerative, 656  
 — of ovaries, 898  
 — of pancreas, 825  
 — of pericardium (*see* Pericarditis), 521  
 — of peritoneum (*see* Peritonitis), 696  
 — of pleura (*see* Pleurisy), 420  
 — of skin (*see* Erysipelas and other skin diseases)  
 — of spleen (*see* Spleen, Inflammation of), 594  
 — of stomach (*see* Gastritis), 666  
 — of thyroid body, 579  
 — of tongue (*see* Glossitis), 646  
 — of tonsils (*see* Quinsy), 648  
 — of trachea (*see* Tracheitis), 396  
 — of urinary bladder, 896  
 — of uterus, 898  
 — of veins (*see* Phlebitis), 565
- Influenza, 147  
 — causation of, 147  
 — complications of, 148  
 — definition of, 147  
 — diagnosis of, 149  
 — duration of, 148  
 — history of, 147  
 — incubation of, 147  
 — morbid anatomy of, 149  
 — mortality of, 149  
 — relations of, with cholera, 147  
 — symptoms and progress of, 147  
 — treatment of, 149
- Innocent, meaning of, as applied to tumours, 31
- Inoculation for small-pox, 171, 180  
 — of specific fevers, 135
- Inorganic murmurs, 511
- Insanity (*see* Madness), 1163, 1190  
 — alcoholic, 623, 1224  
 — of febrile disorders, 1225  
 — puerperal, 1224  
 — of self-abuse, 1225
- Insolatio (*see* Sunstroke), 1165
- Insular sclerosis (*see* Sclerosis, Disseminated), 1063
- Interlobular emphysema (*see* Emphysema), 461
- Intermittent fever (*see* Ague), 283
- Intestinal glands, affection of, in cholera, 242  
 — — — in enteric fever, 228  
 — hemorrhage in enteric fever, 226  
 — worms (*see also* different worms), 717
- Intestines (*see* Bowels)
- Intussusception, 749  
 — causation of, 749  
 — morbid anatomy of, 749  
 — symptoms and progress of, 751  
 — treatment of, 755
- Invagination (*see* Intussusception), 749
- Irritability of paralysed muscles, 974  
 — electric, 1002

## ISC

- Ischuria renalis (*see* Urine, Suppression of), 894  
 Israel on actinomycosis, 735  
 Itch (*see* Scabies), 348  
 — baker's, grocer's, warehouseman's (*see* Eczema), 319

**J**ACCOUD on reflex action, 1089  
 — on affection of speech in small-pox, 178

Jackson, H., on ankle-clonus in epilepsy, 973

- on chorea, 1120  
 — on convulsions, 979  
 — on convulsions in cerebral tumour, 1089  
 — on disease of optic thalamus, 957, 976  
 — on headache, 988  
 — on localisation of cerebral functions, 979

— on retinal vessels in epilepsy, 1132

Jacksonian epilepsy, 1136

Jaundice, 782

- bilious toxæmia in, 785  
 — connected with gall-stones, 816  
 — in ague, 289, 291  
 — in dengue, 201  
 — in heart-disease, 510  
 — in hepatic disease (*see* Hypertrophic Cirrhosis and other diseases)  
 — in pernicious anæmia, 609  
 — in pneumonia, 415  
 — in pyæmia, 273  
 — in relapsing fever, 198  
 — malignant, 822  
 — — causation of, 822  
 — — definition of, 822  
 — — morbid anatomy of, 823  
 — — symptoms and progress of, 824  
 — — treatment of, 824  
 — obstructive, 817  
 — pathology of, 782  
 — symptoms of, 783  
 — without obstruction, 821  
 — — causation of, 821  
 — — morbid anatomy of, 821  
 — — symptoms of, 822  
 — — treatment of, 822  
 — in yellow fever, 203

Jaw-clonus, 972

Jenner, E., on vaccination, 172, 183 *et seq.*

— Sir W., on rickets, 927 *et seq.*

Johne on actinomycosis, 736

Johnson, Geo., on cholera, 244

- on enteric fever, 232  
 — on laryngeal paralysis, 476  
 — on renal disease, 848  
 — on renal dropsy, 101  
 — on sunstroke, 1166  
 — on tests for albumen, 840  
 — on tests for sugar, 836

Joint-affection in gout (*see* Gout), 917 *et seq.*

— in hysteria, 1147

## KID

- Joint-affection in nervous diseases, 983  
 — — in pyæmia, 270 *et seq.*  
 — — in rheumatism (*see* Rheumatism), 906 *et seq.*  
 — — in rheumatoid arthritis (*see* Rheumatoid arthritis), 915 *et seq.*

 — chronic, 651  
 — — symptoms and progress of, 651  
 — — treatment of, 651  
 Quotidian ague, 288

- RABIES** (see Hydrophobia), 246  
**R** Rachitis (see Rickets), 927  
 Radcliffe, N., on cerebro-spinal fever, 205  
 — on cholera, 236  
 Rainey on calcareous deposit, 91  
 — on emphysema, 464  
 Râles, 392  
 Ralfe on albuminuria, 840  
 Ranke on heat of body, 104  
 Ransom on thread-worms, 725  
 Rash (exanthema), 295  
 Rayer on diabetes insipidus, 893  
 Raynaud's disease, 616

## RAY

- Raynaud's disease, causation of, 616  
 — definition of, 616  
 — history of, 616  
 — morbid anatomy of, 616  
 — relations of, to paroxysmal hæmo-  
 globinuria, 618, 883 *et seq.*  
 — symptoms of, 618  
 — varieties of, 616  
 — treatment of, 619  
 Récamier on hemiplegia in cerebral  
 softening, 1106  
 Rectum, ulceration of (*see* Periproctitis),  
 688  
 Recurrent fibroid tumours, 66  
 Red hepatisation of lung, 412 *et seq.*  
 — induration of lung, 432  
 Reduplication of heart's sounds, 516, 849  
 Reflex action in paralysed muscles, 970  
 Relapsing fever, 196  
 — abortion in, 199  
 — causation of, 197  
 — causes of death in, 199  
 — convalescence, protracted in, 199  
 — definition of, 196  
 — history of, 197  
 — incubation of, 197  
 — morbid anatomy of, 199  
 — mortality in, 199  
 — sequelæ of, 199  
 — spirillum in blood in, 138  
 — symptoms and progress of, 197  
 — treatment of, 199  
 Remedial treatment (*see* Therapeutical),  
 124  
 Remittent fever (*see* Ague), 283  
 Renal calculi or concretions, 846, 874  
 — dropsy, 101  
 — diseases (*see* Kidneys, Diseases of),  
 827 *et seq.*  
 Repair, 44  
 Reproductive organs, affection of, in hys-  
 teria, 1147  
 Resonance on percussion, 379, 381  
 Respiration, pathology of, 368  
 Respiratory organs, diseases of, 365 *et*  
*seq.*  
 — in glanders, 253, 254  
 — in leprosy, 280, 282  
 — in pyæmia, 269  
 — tubercle of, 435  
 — causation of, 435  
 — causes of death in, 447  
 — morbid anatomy of, 436  
 — morbid anatomy of cheesy or  
 yellow, 437  
 — morbid anatomy of grey or mi-  
 liary, 437  
 — morbid anatomy of laryngeal,  
 397 *et seq.*, 436  
 — morbid anatomy of pleural, 438  
 — morbid anatomy of pulmonary,  
 436  
 — symptoms and progress, 439

## RIC

- Respiratory organs, tubercle of, symptoms  
 and progress of acute phthisis, 446  
 — symptoms and progress of  
 chronic phthisis, 446  
 — symptoms and progress of pleu-  
 ral tubercle, 447  
 — treatment of, 447  
 Retina, anæmia of, in epilepsy, 1132  
 Retinal hemorrhage in leucocythæmia,  
 606  
 — in pernicious anæmia, 609  
 — in purpura, 615  
 — in renal disease, 849  
 Retro-pharyngeal abscess, 651  
 — causation of, 651  
 — symptoms and progress of, 651  
 — treatment of, 652  
 Reynolds, R., on epilepsy, 1123 *et seq.*  
 — on hysterical paralysis, 1151  
 Rheumatic fever (*see* Rheumatism), 906  
 — nodules, 907  
 Rheumatism, 906  
 — causation of, 906  
 — chorea in relation with, 1116  
 — complications of, 910  
 — definition of, 906  
 — deltoid (*see* Deltoid Rheumatism),  
 1181  
 — heart-disease in, 910  
 — lumbago, 908  
 — morbid anatomy of, 906  
 — pathology of, 912  
 — scarlet fever in relation with, 169  
 — sciatica, 908  
 — symptoms and progress of, 908  
 — torticollis, 908  
 — treatment of, 913  
 Rheumatoid arthritis, 915  
 — causation of, 915  
 — definition of, 915  
 — morbid anatomy of, 915  
 — pathology of, 917  
 — symptoms and progress of, 917  
 — treatment of, 917  
 Rhonchus, 393  
 Rhythmical movements, 1152  
 — treatment of, 1154  
 — tremors in disseminated sclerosis,  
 1065  
 — in lateral sclerosis, 1045 *et seq.*  
 — in mercurialism, 633  
 — in paralysis agitans, 1075 *et seq.*  
 Richardson on tetanus, 1158  
 Rickets, 927  
 — causation of, 927  
 — definition of, 927  
 — morbid anatomy of, 927  
 — pathology of, 927

 — treatment of, 933  
 — acute, 933  
 — causation, 934  
 — definition, 933

## RIC

- Rickets, acute, morbid anatomy, 934  
 — — symptoms and progress, 934  
 — — treatment, 935  
 Ricord on syphilis, 255  
 Rigidity, muscular, in lateral sclerosis, 1045 *et seq.*  
 — — in paralysis agitans, 1077  
 (See also various other affections of the Cord and Brain)  
 Rigors, 109  
 (See also Ague and other febrile and inflammatory disorders)  
 Rilliet and Barthez on rickets, 932  
 Rindfleisch on calcareous degeneration, 90  
 — on carcinoma, 68  
 — on epithelioma, 73  
 — on lardaceous liver, 810  
 — on mollities ossium, 936  
 — on proud flesh, 44  
 — on tubercle, 76  
 Ringworm (*see* Tinea Tonsurans), 353  
 Risus sardonius in rheumatism, 911  
 — — in spinal meningitis, 1022  
 — — in tetanus, 1156  
 Roberts, Sir W., on alkalinity of urine, 828  
 — on chyluria, 881  
 — on diabetes insipidus, 893  
 — on phosphates in urine, 838  
 — on suppression of urine, 895  
 — on tests for albumen, 840  
 — on uric acid calculi, 877  
 Rodent ulcer, 343  
 Roe, H., on treatment of whooping-cough, 153  
 Roger on chorea, 1116  
 — on rickets, 932  
 Rokitsanski on dysentery, 681  
 Roseola (*see* Erythema), 306, 309  
 — epidemic (*see* Epidemic Roseola), 160  
 Rötheln (*see* Epidemic Roseola), 160  
 Round worms, 725  
 — — common, description of, 725  
 — — — symptoms of, 726  
 — — — treatment of, 726  
 Rubeola (*see* Epidemic Roseola and Measles), 156, 160  
 Rupia, 328  
 — causation and description of, 328  
 — escharotica, 328  
 — prominens, 328  
 — simplex, 328  
 — treatment of, 329
- S**T. VITUS'S DANCE (*see* Chorea), 1116  
 Salisbury on palmellæ as cause of ague, 285  
 Salivary glands, affection of, in mumps, 154  
 Salter, Hyde, on asthma, 479 *et seq.*

## SCH

- Sanderson, Burdon, on cholera (experimental production of), 237  
 — on contagium, 138  
 — on febrile process, 106  
 — on lymphatic tissue, 62, 77  
 — on septic organisms in inflammation, 48  
 — on tubercle, 77

- pulsation, 510
- sinuses, obstruction of, 1006, 1009, 1090

## Ventricles of brain and cord, anatomy of, 940

- — dropsy of (*see* Hydrocephalus and Hydrorrhachis), 1110
- — effusion of blood into, 1096, 1101
- of heart, diseases of (*see* Heart, &c.)

## Verruca necrogenica, 341

Vertebræ, caries of (*see* Dura Mater, Inflammation of), 1006, 1011

## Vertigo, 989

- aural (*see* Ménière's Disease), 1170
- in disseminated sclerosis, 1066
- epileptic, 1127
- in morbid growths of brain, 1087
- pathology of, 989
- varieties of, 989

## Vesicles, meaning of term, 296

## Vesiculæ (Willan's sixth order), 297

Vesicular emphysema (*see* Emphysema), 461

## Vibices, meaning of term, 295

## Villemain on inoculation of tubercle, 80

Virchow on carcinoma, 67 *et seq.*

- on catarrh of hepatic ducts, 821
- on cell-districts, 20
- on classification of tumours, 51
- on cloudy swelling, 83
- on cretinism, 584 *et seq.*
- on elephantiasis Arabum, 60, 338
- on enchondroma, 56
- on erysipelas, 301
- on fibrine in inflammation, 30
- on glioma, 55
- on goitre, 580 *et seq.*
- on granuloma, 74
- on hyperplasia, 32
- on jaundice, 783
- on keloid, 333
- on inflammation, 49

## VIR

- Virchow on lardaceous degeneration, 85  
 — on leprosy, 281, 282  
 — on lymphoma, 60  
 — on mollities ossium, 936  
 — on molluscum contagiosum, 340  
 — on myeline, 93  
 — on physiological tissues, 19  
 — on psammoma, 67  
 — on pyæmia, 272  
 — on sarcoma, 64  
 — on seat of origin of morbid growths, 28  
 — on syphilitic disease of liver, 799  
 — on tongue-enlargement in children, 603  
 — on tubercle, 78  
 — on tubercle of oral mucous membrane, 653  
 — on ulcer of stomach, 676  
 — on white hepatisation of lungs, 451  
 Vital causes of disease, 16  
 — properties of protoplasm, 18  
 Vitiligoidea (*see* Xanthoma), 334  
 Vocal fremitus, 377  
 Voelcker on centres for movements of internal ocular muscles, 1061  
 Vogel, Alfred, on urea in pyæmia, 107  
 Voice, absence of, 368  
 — auscultation of, 386, 390  
 — in cholera, 239  
 — compass of, 368  
 — feebleness of, 367  
 — in leprosy, 280  
 — pathology of, 367  
 — pitch of, 368  
 — quality of, 368  
 Volkman on infantile paralysis, 1036  
 Vomica, detection of, 395  
 (*See also* Pneumonia, Cirrhosis, Tubercular Disease, and Morbid Growths of the Lungs)  
 Vomit, black, in yellow fever, 203  
 Vomiting of blood (*see* Hemorrhage from Stomach), 762  
 — in dyspepsia, 768  
 — in epidemic cholera, 238  
 — in hysteria, 1145  
 — in megrim, 1167  
 — in Ménière's disease, 1171  
 — in morbid growths of brain, 1087  
 — in obstruction of bowels, 753  
 — in obstruction of stomach, 739  
 — in tubercular meningitis, 1017 *et seq.*  
 (*See also* various affections, especially of stomach and bowels)  
 Von Bärensprung on erythrasma, 359  
 — — on zona, 324

## WRY

- Wasting palsy (*see* Muscular Atrophy, Progressive), 1040  
 Water on the brain (*see* Hydrocephalus), 1110  
 — on the chest (*see* Hydrothorax, 468, and Hydropericardium, 540)  
 Water-brash, 769  
 Watson, Eben, on nitrate of silver in whooping-cough, 154  
 Watson, Sir Thomas, on ague, 284 *et seq.*  
 — on apoplexy, 1103  
 — on catarrh, 638  
 — on chorea, 1118 *et seq.*  
 — on hydrocephalus, 1115  
 — on hysteria, 1145, 1150  
 — on lead-poisoning, 632  
 — on meningitis, 1024  
 — on recurrent palpitation, 544  
 — on tetanus, 1155 *et seq.*  
 Watson, Spencer, on cystic goitre, 580  
 Watteville, Dr. de, on reflex action, 972  
 Wavy respiration, 395  
 Waxy degeneration, 84  
 Weber, H., on hyperpyrexia, 911  
 Wens, 330  
 Werlhofii, morbus maculosus (*see* Purpura), 614  
 West, C., on infantile convulsions, 1136  
 — on infantile paralysis, 1035  
 Westphal on acute ascending spinal paralysis, 1038  
 — on affection of speech in small-pox, 178  
 — on tendon reflexes, 971  
 Wheal, definition of, 296  
 Whipham on affection of speech in small-pox, 178  
 Whip-worm, 727  
 White hepatisation of lungs, 451  
 White-cell blood (*see* Leucocythæmia), 604  
 Wilks on delirium tremens, 626  
 — on encephalitis, 1027  
 — on verruca necrogenica, 341  
 Willan on classification of skin diseases, 294 *et seq.*  
 — on erythema and roseola, 306 *et seq.*  
 — on lepra and psoriasis, 311 *et seq.*  
 — on prurigo, 363  
 — on strophulus albidus, 330  
 — on urticaria, 310  
 Wilson on classification of skin diseases, 294  
 — on ichthyosis, 314  
 — on lichen planus, 317  
 Worms, intestinal, 717 *et seq.*  
 Wrist-drop (*see* Lead-poisoning), 629 *et seq.*  
 Writer's cramp, 1182  
 — — causation of, 1182  
 — — definition of, 1182  
 — — pathology of, 1185  
 — — symptoms and diagnosis of, 1183  
 — — treatment of, 1185  
 Wry-neck, spasmodic, 1182  
 — causation of, 1182

**WAGSTAFFE** on collapse temperatures, 116

Waller, Augustus, on tendon reflex, 972

Warehouseman's itch, 319

Warner on rheumatic nodules, 907

## WRY

- Wry-neck, definition of, 1182  
 — pathology of, 1185  
 — symptoms and diagnosis of, 1183  
 — treatment of, 1185  
 Wunderlich on temperature in enteric fever, 225

**X**ANTHELASMA (*see* Xanthoma), 334

- Xanthine calculi, 847  
 — chemistry of, 834  
 Xanthoma, 334  
 — causation of, 334  
 — connection with diabetes, 335  
 — connection with jaundice, 337, 785  
 — description of, 334  
 — planum, 334  
 — tuberosum, 334  
 Xerodermia (*see* Ichthyosis), 314

**Y**EAST fungus in urine, 846  
 — — in vomit, 715, 740, 769

## ZYM

- Yellow atrophy of liver (*see* Jaundice, Malignant), 822  
 — fever, 202  
 — — causation of, 202  
 — — death, causes of, in, 203  
 — — definition of, 202  
 — — diagnosis of, 203  
 — — history of, 202  
 — — incubation of, 202  
 — — morbid anatomy of, 204  
 — — mortality of, 203  
 — — symptoms and progress of, 202  
 — — treatment of, 204

**Z**ENKER on degeneration of muscle, 84

— — on trichinosis, 729

Ziemssen, von, on depressors of epiglottis, 475

Zona (*see* Herpes Zoster), 324

Zoster (*see* Herpes Zoster), 324

Zymotic diseases (*see* Specific Febrile Diseases), 133
